# ABSTRACT

---

To avoid the high costs and environmental and regulatory challenges of building new lines to meet the power demand, utilities are searching for ways to increase power transmission capacity on existing lines and thereby. This could involve upgrading the network lines with conductors capable of transmitting greater capacity. In recent years, conductor manufacturers have begun producing new conductors that can operate at higher temperatures without violating present electrical clearances to ground and other objects. One new conductor technology is a carbon composite core with PPS polymer matrix and PEEK capping layer composite conductor, manufactured by Southwire Inc. The conductor uses new materials, which have not previously been used for overhead lines.

The project made an initial characterization of the composite core to define the material used in the manufacture of the composite. Several analytical procedures were then conducted to evaluate the physical-chemical impacts on the composite as a result of thermal exposure. These procedures included thermogravimetry, dynamic mechanical analysis, thermal mechanical analyses, and optical microscopy. Mechanical three-point flexural tests, tensile tests, creep tests, and dynamic vibration tests were then performed to estimate the potential degradation after thermal aging.

The report provides the basis to develop a qualification testing protocol for the carbon composite core at targeted service environments. The work covers the design of the qualification testing protocol and the follow-on validation testing to support the proposed methods. The research includes the following approaches: initial characterization, performance of thermal aging, characterization of the aged material, comparison of aged properties or characteristics to the original, and concluding by the findings through the developed qualification procedures.

# 1 INTRODUCTION

---

To avoid the environmental, regulatory and high costs challenges of building new lines to meet the power demand, utilities are searching for ways to increase power transmission capacity on existing lines and thereby. This could involve upgrading the network lines with conductors capable of transmitting greater capacity. In recent years, conductor manufacturers have begun producing new conductors that can operate at higher temperatures without violating present electrical clearances to ground and other objects. One new conductor technology, C7 aluminum conductor, its core is made of carbon fibers with PPS polymer matrix and PEEK capping layer composite, manufactured by Southwire Inc. The C7 conductor composite core materials have not been used previously for overhead lines. Some preliminary background on this C7 composite core conductor provided by Southwire and Composite manufacturer are discussed in this section.

## 1.1 Background

To increase power transmission capacity on existing lines, one approach would involve upgrading the transfer capacity through reconductoring of selected network lines with conductors capable of transmitting greater capacity. This approach can only be adopted if the long-term durability of the constituent equipment can be demonstrated. If the new conductors are used, the maximum operating temperature of overhead lines (Joule effect losses), which is currently around 70-90°C in ambient air, would then rise above 100°C, and could exceed 180°C. Where Southwire's C7 Overhead Conductor is one of such advanced conductors, as shown in Figure 1.

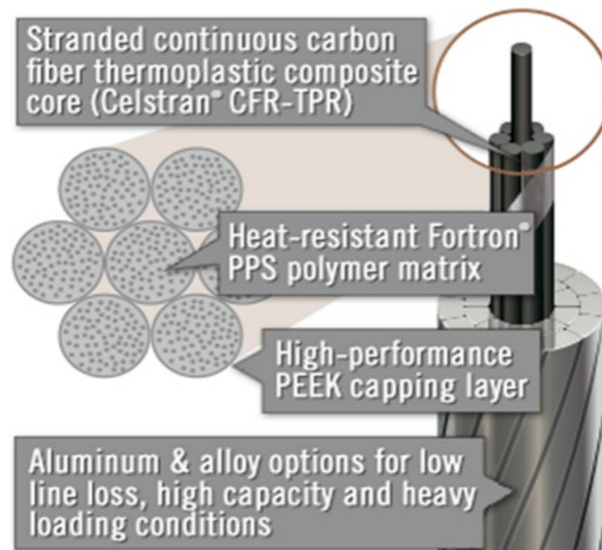

Figure 1 Southwire C7 Composite-core Conductor. [1]

This Southwire's newest transmission conductor is the result of a partnership with Celanese Corporation — engineers of advanced polymers, resins and thermoplastics. The C7 Overhead Conductor uses Celanese Celstran® CFR-TPR (continuous fiber reinforced thermoplastic strands) composite technology that involves an innovative combination of carbon fiber and a high-temperature Fortron® PPS (polyphenylene sulfide) matrix that is capped with a layer of high-performance PEEK (polyether ether ketone). C7 Overhead Conductor, shown in Figure 1, features a multi-stranded, carbon-fiber composite core. Southwire has claimed that its advanced core and polymer coating provides C7 Overhead Conductor with high heat resistance and a target 40+ year service life expectancy. [2] Furthermore, regarding C7 overhead conductor performance and installation the vendor also stated that “C7 Overhead Conductor is engineered to withstand the rigors of installation and operation as stated below:

“Utility providers can reduce new-line costs by installing with standard line tools on existing structures and foundations. Reconductoring is also more affordable, as C7 Overhead Conductor has nearly double the capacity with less sag than same-diameter ACSR.”

The expected good performance of C7 Overhead Conductor primarily relies on the advanced carbon composite core mechanical performance per vendor’s specifications. Nevertheless, the application of the conventional crimping process for building the splice connector of C7 carbon composite core may need a closer examination to ensure its long-term reliability under lateral compressive clapping stresses.

The purpose of the proposed project is to develop a qualification testing protocol that can effectively evaluate the C7 Overhead Conductor carbon composite core integrity and reliability at the targeted service environments or beyond.

## **1.2 General Consideration of Thermoplastic Polymers Characterizations**

In addition to first-order phase transitions such as melting and vaporization, there are second-order transitions that occur in certain materials. One of these second-order transitions is the glass transition exhibited by amorphous materials. When amorphous materials are cooled below their glass transition temperatures, they become hard and brittle, like glass; when the amorphous materials are heated above their glass transition temperatures, they are in the rubbery state, where they are soft and flexible.

This glass transition phenomenon is mainly because the molecular chains become entangled and cannot slip pass each other at low temperatures. The temperature at which the molecular chains become ‘locked’ upon cooling or ‘released’ upon heating is referred to as the glass transition temperature (T<sub>g</sub>).

Rheological testing of thermoplastic materials can be performed on both solid samples and melts. This is important because the choice of material form and physical state is more than a matter of convenience. Where product performance issues usually are related to solid samples properties and process ability issues can be correlated with polymer melt properties. Mechanical spectroscopy is the study of time-dependent responses of stress or strain to various external time-dependent mechanical perturbations. [3] Thermoplastic solids, such as PPS and PEEK, are tested using mechanical spectroscopy to study polymer morphology and structure and relate these to end-use performance. Accurate solid-state measurements of the material’s T<sub>g</sub>, modulus (G’) and

damping ( $\tan \delta$ ) are used to predict practical use temperatures, impact properties, energy dissipation, stiffness and many other performance properties.

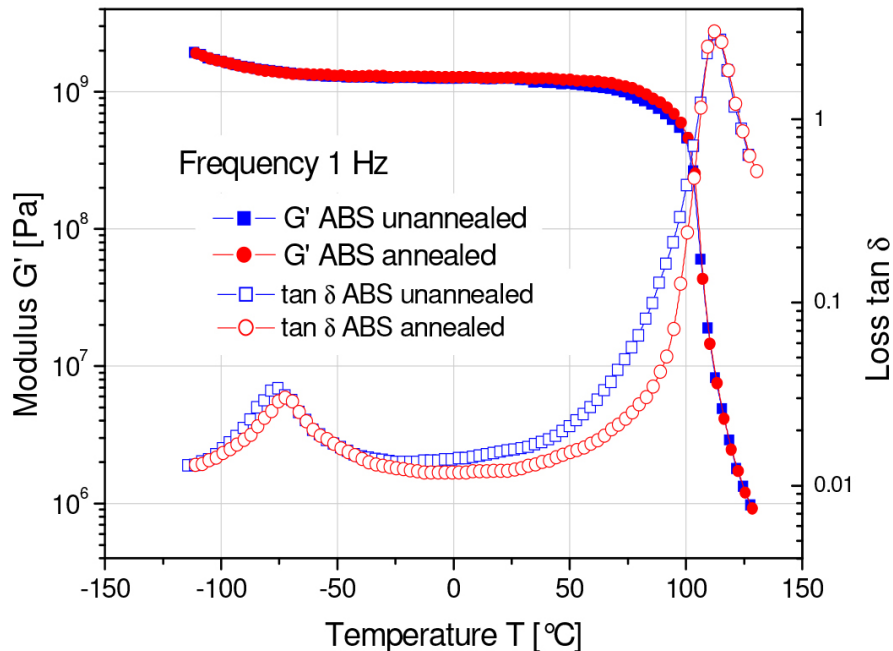

Physically, the  $T_g$  is the point at which polymer chains gain enough energy in order to substantially increase their mobility within the polymer matrix and this is reflected in a sharp change in material flexibility and an increase in the sample's heat capacity. The  $T_g$  is a key property of thermoplastic systems and often defines the temperature range in which the thermoplastic materials may be used. Parameters that will affect the  $T_g$  of a thermoplastic system include the polymer resin and hardener chemical structure, degree of cure, and moisture content. Understanding the glass transition temperature can therefore be critical for determining material suitability for specific applications.

One of the most common methods for measuring a polymer's  $T_g$  is by Differential Scanning Calorimetry (DSC), in which the changes in heat capacity through the  $T_g$  result in a sigmoidal change in the heat flow signal indicating that a glass transition has occurred. However, this technique often lacks the sensitivity to adequately identify the glass transition temperature, and in some cases may conclude that a material has no glass transition temperature at all. It can also be confounded in complex systems by other thermal transitions occurring in the material.

### 1.2.1 Dynamic Mechanical Analysis

An alternative common method for measuring  $T_g$  is by Dynamic Mechanical Analysis (DMA). In this test, the sample is subjected to an oscillatory stress, and the material response is measured. The nature of this response may be used to determine the elastic and viscous properties of the material (storage modulus and loss modulus, respectively), and this can be very sensitive to  $T_g$  as the material rapidly becomes more flexible at the transition temperature. A third parameter, tangent delta is defined as the ratio between the loss modulus and the storage modulus and represents the relative contribution of the viscous vs. elastic properties. During a DMA experiment, the sample temperature is slowly scanned, and the storage modulus, loss modulus, and  $\tan \delta$  are continuously measured. At the glass transition temperature, the storage modulus is observed to decrease sharply, and a peak is observed in both the loss modulus and  $\tan \delta$  signals. Thus, DMA testing is considered the most sensitive method for measuring the glass transition and secondary transitions of polymers. Moreover, rheological properties can be measured continuously as the material undergoes temperature-induced changes from amorphous to crystalline; solid to molten and vice versa.

Figure 2 shows a DMA trace on freshly molded samples and companion pieces annealed under vacuum for eight hours at 180°C. The storage modulus  $G'$  and  $\tan \delta$  were measured at a frequency of 1 Hz and a strain of 0.07% at temperatures from 120°C to 130°C. Clear differences were found between the annealed and unannealed samples near the main glass transition: the sample with residual strains had a higher  $\tan \delta$  over a wide range of temperatures below the glass transition temperature  $T_g$ . This relates to the relaxation of the backbone conformations of the oriented styrene-acrylonitrile component in the continuous phase. [3]

**Figure 2. Effect of annealing on loss tangent of an injection molded ABS part. [3]**

A quick overview on the rheological properties evolution is provided in Figure 3. [4] Moving from very low temperature, where the molecule is tightly compressed, to a higher temperature, the first changes are the solid-state transitions. This process is shown in Figure 3. As the material warms and expands, the free volume increases so that localized bond movements (bending and stretching) and side chain movements can occur. This is the gamma transition,  $T_\gamma$ , which may also involve associations with water. As the temperature and the free volume continue to increase, the whole side chains and localized groups of 4-8 backbone atoms begin to have enough space to move and the material starts to develop some toughness. This transition, called the beta transition  $T_\beta$ , is not as clearly defined as described here. Often it is the  $T_g$  of a secondary component in a blend or of a specific block in a block copolymer. However, a correlation with toughness is seen empirically. As heating continues, the  $T_g$ , or glass transition, appears when the chains in the amorphous regions begin to coordinate large-scale motions. One classical description of this region is that the amorphous regions have begun to melt. Since the  $T_g$  only occurs in an amorphous material, in a 100% crystalline material there would not be a  $T_g$ . Continued heating drives the material through the  $T_{\alpha^*}$  and  $T_{II}$ . The former occurs in crystalline or semi-crystalline polymer and is a slippage of the crystallites past each other. The latter is a movement of coordinated segments in the amorphous phase that relates to reduced viscosity. These two transitions are not universally accepted. Finally, the melt is reached where large-scale chain slippage occurs and the material flows. This is the melting temperature,  $T_m$ . For a cured thermoset, nothing happens after the  $T_g$  until the sample begins to burn and degrade because the crosslinks prevent the chains from slipping past each other.

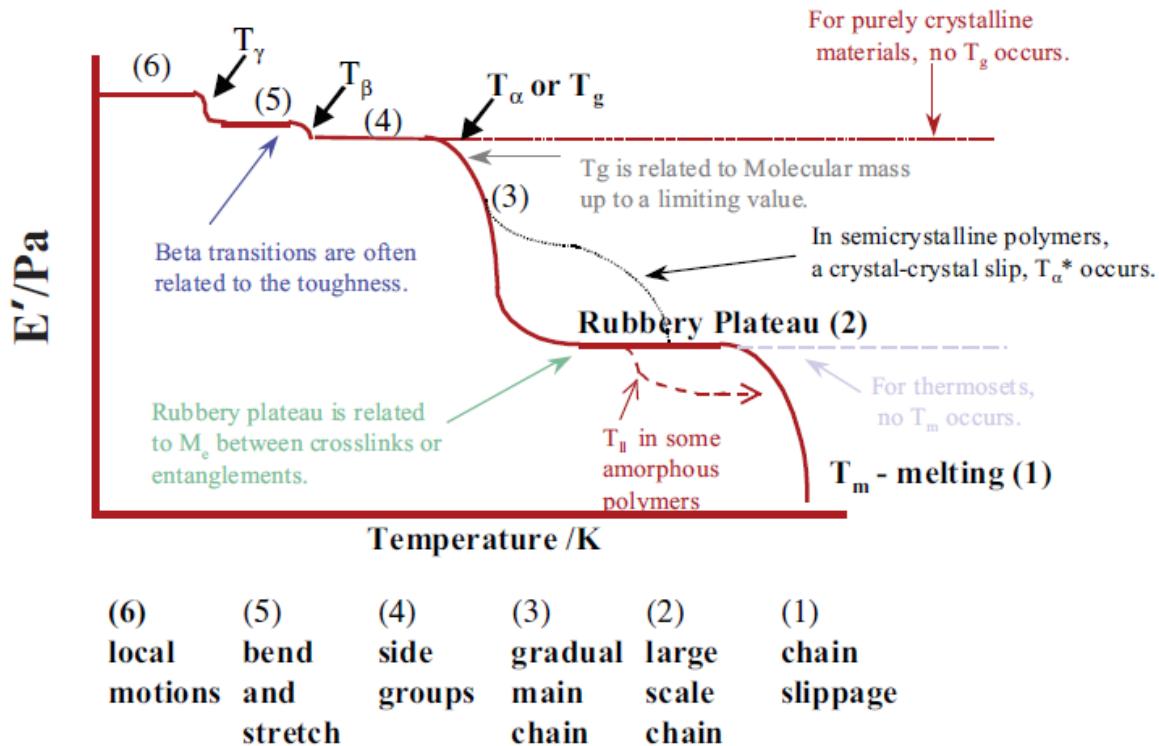

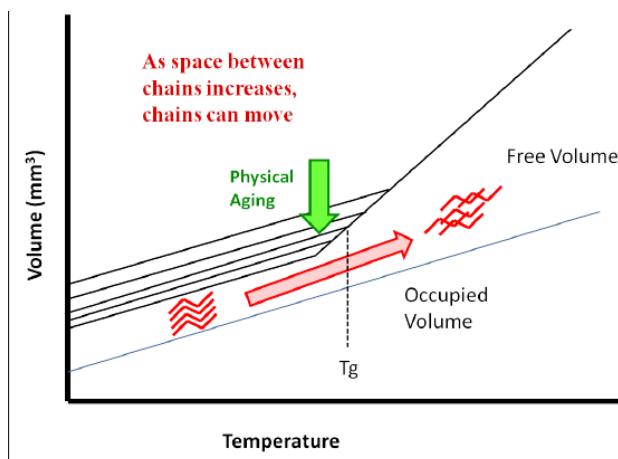

Figure 3. An idealized DMA scan showing types of transitions seen in the DMA 8000. [4]

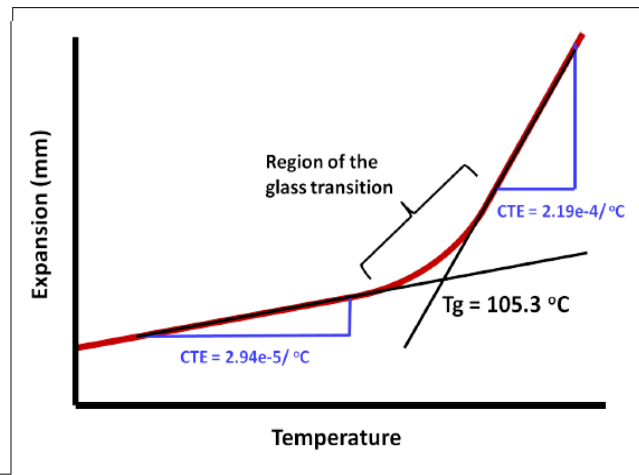

### 1.2.2 Thermomechanical Analysis

Thermomechanical Analysis (TMA) is one of the most basic tools of material science that can also be used to assist thermoplastic material characterization. [5] The basis of TMA is the change in the dimensions of a sample as a function of temperature. TMA measurements record changes caused by changes in the free volume of a polymer. Changes in free volume,  $v_f$ , can be monitored as a volumetric change in the polymer; the loss of stiffness; increased flow; or by the change in relaxation time. The free volume of a polymer,  $v_f$ , is known to be related to viscoelasticity, aging, penetration by solvents, and impact properties. The  $T_g$  in a polymer corresponds to the point in the expansion curve where the free volume begins to allow for greater chain mobility (Figure 4). Seen as an inflection or bend in the thermal expansion curve, this change in the TMA can be seen to cover a range of temperatures, for which the  $T_g$  temperature is a somewhat arbitrary indicator calculated by an agreed upon method (Figure 5). This fact seems to be not appreciated by inexperienced users, who often worry why perfect agreement isn't seen in the value of the  $T_g$  when comparing different thermal methods. The width of the  $T_g$  region can be as important an indicator of changes in the material as the actual temperature.

Experimentally, TMA consists of an analytical train that allows precise measurements of position and can be calibrated against known standards. A temperature control system of a furnace, heat sink and temperature measuring device (most commonly a thermocouple) couples to the sample. Fixtures to hold the sample during the run are normally made of quartz because of its low CTE, although ceramics and invar steels may also be used. Fixtures are commercially available for expansion, three-point bending or flexure, parallel plate, and penetration tests.

**Figure 4.** The increase in free volume is caused by increased energy absorbed in the chains, and this increased free volume permits the various types of chain movement to occur. Below the  $T_g$  various paths with different free volumes exist depending on heat history and processing of the polymer, where the path with the least free volume is the most relaxed.

**Figure 5.** The glass transition and CTE of polystyrene is shown. The slopes of the baseline are used to calculate the CTE. The  $T_g$  is a region of between 90 and 110 °C, for which a  $T_g$  temperature is calculated as shown. [5]

### 1.2.3 Thermogravimetric analysis

Thermogravimetric analysis (TGA) is one of the members of the family of thermal analysis techniques used to characterize a wide variety of materials. TGA provides complimentary and supplementary characterization information to the most commonly used thermal technique, DSC.

TGA measures the amount and rate of change in the mass of a sample as a function of temperature or time in a controlled atmosphere. The measurements are used primarily to determine the thermal and/or oxidative stabilities of materials as well as their compositional properties. The technique can analyze materials that exhibit either mass loss or gain due to decomposition, oxidation or loss of volatiles (such as moisture). It is especially useful for the study of polymeric materials, including thermoplastics, thermosets, elastomers, composites, films, fibers, coatings and paints w.r.t. (1) compositional analysis of multi-component materials or blends, (2) thermal stabilities, (3) oxidative stabilities, (4) estimation of product lifetimes, and (5) decomposition kinetics.

### **1.3 Proposed Research Objectives**

To develop a qualification testing protocol for the carbon composite core at targeted service environments is the primary objective of this project. The work covers the design of the carbon core qualification testing protocol and the follow-on validation testing to support the proposed testing protocols. The research will include the following approaches: initial characterization, performance of thermal aging, characterization of the aged material, comparison of aged properties or characteristics to the original, and concluding by developing acceptance criteria. Due to composite nature of C7 carbon composite core, the interface shear behavior at PEEK and PPS matrix boundary plays a critical role in overall C7 core performance. This would limit our options of selecting C7 core sample dimension/geometry to ensure such composite system performance can be effectively characterized from the elected tested sample, and the associated geometry dependent mechanical testing. Thus, the single C7 core wire consisted both PEEK capping layer and PPS matrix with system diameter of 3.45-mm was elected to be the sample profile used in the following analyses and program development. The C7 core system bonding shear stress effect at interface of PEEK layer and PPS matrix can be effectively characterized through a 3-point bending flexural testing on the C7 core test sample configuration. Thus, 3-point bending test was elected as one of the primary mechanical testing protocols used for characterizing the C7 composite core performance under the targeted service environments.

### **1.4 Proposed Research Tasks Descriptions**

#### **Task 1. Review and Evaluate Existing Polyphenylene sulfide (PPS) Polymer and PolyEtherEther Ketone (PEEK) Properties**

In this task, ORNL will review and summarize the various mechanical and chemical properties of carbon composite related to composite core used for Southwire C7 Overhead Conductor. The study shall cover high-temperature performance of the resins (PPS and PEEK) used in composite.

#### **Task 2. Develop Test Protocols to Validate C7 Conductor Carbon Composite Core Performance**

ORNL will develop testing protocols for C7 Overhead Conductor composite core material under targeted temperatures and loading conditions to determine whether the composite core materials can meet its performance requirements. ORNL will identify appropriate material mechanical property in the pilot program development, including time-dependent mechanical properties for C7 Conductor composite core.

The following subjects will be investigated.

- a) Stability of the material in service conditions (heat) – study of the thermal degradation (chemical changes in the composite)
- b) Impact of the aging phenomenon on the long-term behavior – evaluation of the effect of the chemical change on the long-term mechanical behavior

- c) Impact of the thermal cycling (operation temperatures) and prediction of the service life expectancy.

The proposed approaches for developing testing protocols are detailed below.

- 1) Sample design and preparation, including a mold for forming the rectangular C7 carbon composite sample for Dynamic Mechanical Analysis (DMA), Thermogravimetric Analysis (TGA), and Thermal-mechanical Analysis (TMA) testing, and test fixtures design & manufacturing for the specific mechanical testing.
- 2) Initial characterization – knowledge of the resin, type of the resin, and ratio of matrix-fiber, etc. will also examine specimen design for the specific testing.
- 3) Performing thermal aging
  - Carbon composite core 10 mm long in TGA apparatus for 100 hours at 100°C
  - Samples 100 mm long in an oven in the air;

Temp stability	Temp max
500 hours	100 hours

- 4) Thermal aging characterization:

From sample aged in TGA apparatus with sample dimension of 10 mm long

Techniques	Characteristics	Number and type of samples
TGA	Loss of weight versus time at 100, 180, 225 °C	3 samples (C7 core 10 mm long)
DMA	Tg (Storage, Loss modulus, and damping coefficient)	3 samples: rectangular or circular rod machined from carbon core

For samples aged in oven under air is described below.

Techniques	Characteristics	Number and type of samples
Microscopy analysis	Presence of cracks Homogeneity of the material	3 samples of 100 mm long coming out of aging program + new one. Surface polished and then checked
3-point flexural ASTM D790	Maximum load & sag of the sample during the test	3 samples of 100 mm long per time-temperature

- 5) Qualification criteria – Glass Transition Temperature (Tg), mechanical tensile test, 3-point bending test, and creep testing.

**Task 3: Establish Acceptance Criteria**

ORNL will establish initial acceptance criteria and final validation of the developed criteria from the developed testing database.

**Task 4: Attend Semi-Annual Task Force Meetings and Conference Calls**

ORNL will present the results at various stages of the study to EPRI members at project review meetings and participate in conference calls as required.

## 2 PRELIMINARY CHARACTERIZATION OF C7 CONDUCTOR CARBON COMPOSITE CORE

The key benefits and characteristics of C7 overhead conductor discussed in Southwire C7 Overhead Conductor Innovation [1] are the followings:

- Minimal thermal expansion – minimal sag increase at high power transfer
- Stranded core – no single point of failure
- Flexible – robust, installs like a traditional conductor
- Less sag – for lines with clearance or structure limitations
- Thermoplastic resins – long usage history in demanding applications with established high-temperature performance (180-225°C)
- Conventional connectors – traditional two-piece compression, crew friendly
- Designs for all loading conditions – light loading to extreme ice loading
- Trapezoidal wire (TW), Zirconium Aluminum (Zr-Al) and O-temper versions

Those key advantages mentioned above were further examined and validated through the proposed testing protocols. The detailed properties of PPS and PEEK polymer, and C7 carbon composite provided by the vendors are discussed in this section

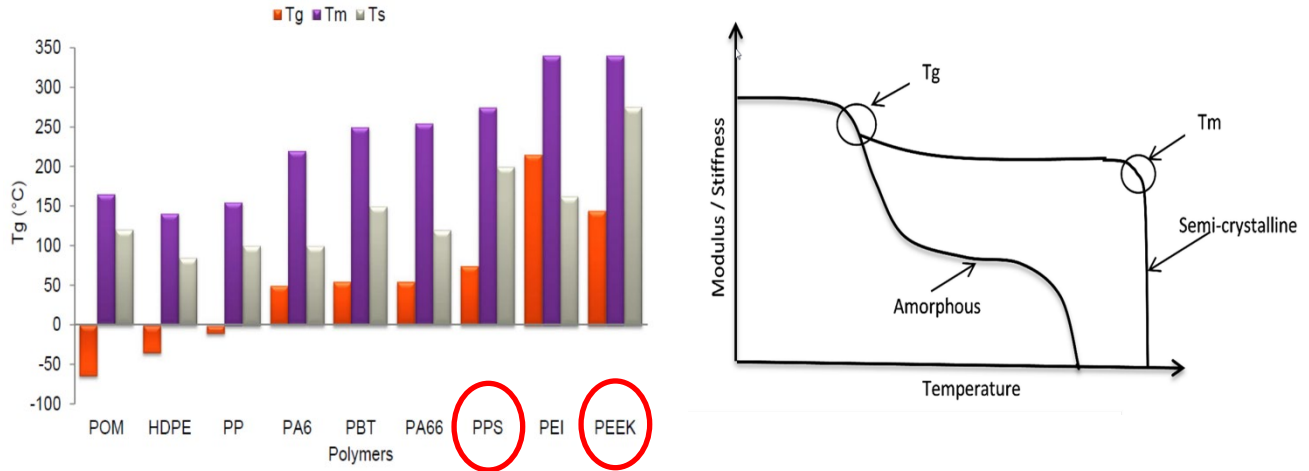

### 2.1 C7 overhead conductor system components technical specifications

A thermoplastic, such as PPS or PEEK, is a plastic material, a polymer, that becomes pliable or moldable above a specific temperature and solidifies upon cooling. Most thermoplastics have a high molecular weight. The polymer chains associate through intermolecular forces, which weaken rapidly with increased temperature, yielding a viscous liquid. Thus, thermoplastics may be reshaped by heating and are typically used to produce parts by various polymer processing techniques. Thermoplastics differ from thermosetting polymers, such as epoxy, which form irreversible chemical bonds during the curing process. Thermosets do not melt when heated: they decompose and do not reform upon cooling. Table 1 and Figure 6 show thermal key points of thermoplastic of polymer, including PPS and PEEK polymers.

**Table 1 Thermoplastic Polymer Characteristics, used in Composite. [6]**

Polymer	Tg	Process Temperature	Morphology
PEEK	143°C	380-395°C	Semi-Crystalline
PPS	89°C	290-325°C	Semi-Crystalline
PEI	217°C	300-330°C	Amorphous
PEKK	156°C	340-365°C	Semi-Crystalline
Nylon-6	47°C	210-230°C	Semi-Crystalline
Nylon-11	42°C	180-205°C	Semi-Crystalline

Figure 6 shows that the Tg for PPS and PEEK are 89°C and 143°C, respectively; and the melting temperature (Tm) for PPS and PEEK are 275°C and 335°C, respectively. The modulus thermal aging history also indicates that semi-crystalline thermoplastic, such as PPS and PEEK have different aging characteristic compared to amorphous thermoplastic polymers.

**Figure 6 (Left) Thermal key points of different thermoplastic polymers, (Right) the schematic diagram illustrated the determination of Tg and Tm from DMA test for semi-crystalline materials, such as PPS and PEEK polymers. [6]**

Table 2 show thermoplastic polymer composite reinforced with carbon fiber, where PPS-CF45 and PPS-CF51 are similar to that of C7 composite core materials, with CF volumes at 37% and 43%, respectively. It is noted that C7 composite core extension of 2% total strain was reached before failure. The elevated tensile and thermal aging properties of the uncapped PPS and PEEK polymers carbon composites are shown in Figures 7-8.

## 2.2 Initial C7 carbon composite core physical examinations

The microscopy, scanning electron microscope (SEM), and energy dispersive spectroscopy (EDS) examinations of the received C7 carbon composite core samples from EPRI are shown in Figs 9-15. Large variation of carbon fiber distribution with PPS was observed, which shows the inhomogeneous characteristic of C7 composite core, where the carbon fiber (CF) volume ratio ranges are from 28% to 51% from different sections of the C7 composite core sample.

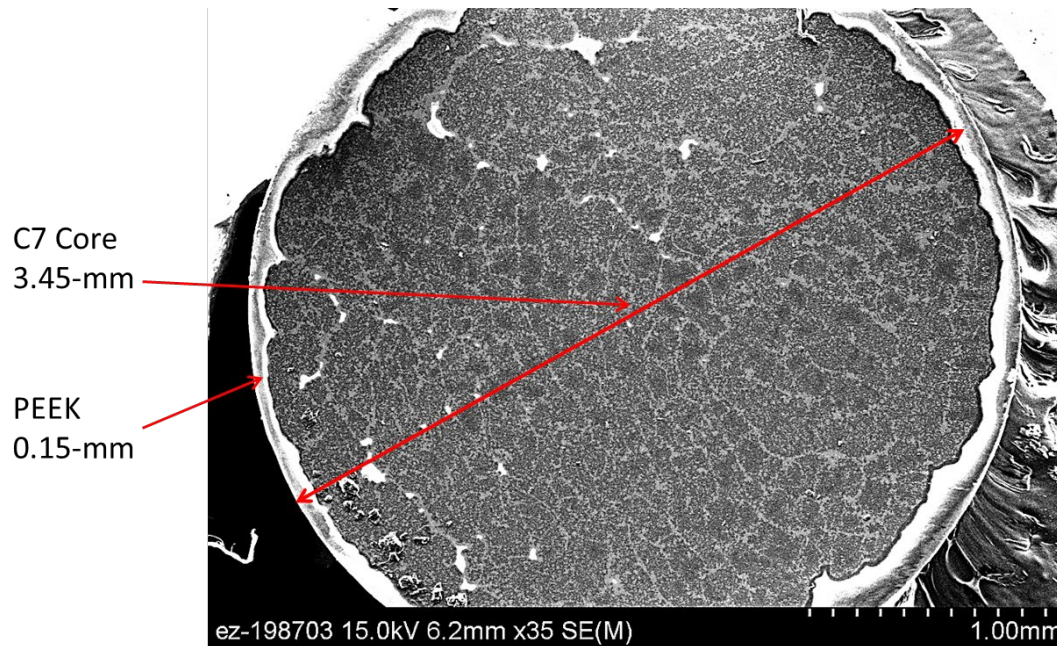

Figure 9 Microscopy image of the cross-section of the received C7 composite core samples.

### 3 THERMAL AGING EXPERIMENTS AND THERMAL AGING CHARACTERIZATIONS USING TGA, DMA, AND TMA TECHNIQUES

The thermal aging experiments were carried out on C7 carbon composite core in TGA apparatus heating up to 700°C; in TGA apparatus for 100 hours at 100°C, 180°C and 225°C under nitrogen and under air, respectively. The thermal aging characterizations were performed on C7 carbon composite core samples aged in TGA, DMA, TMA apparatuses, the test results and the associated aging techniques characteristics are discussed in this section.

Techniques	Characteristics	Planed Number of samples
TGA	Loss of weight versus temperatures	3 samples (carbon core wire)
DMA	Tg (Storage, Loss modulus, and Damping factor- Tan $\delta$ )	3 samples: (carbon core wire)
TMA	Tg (Thermal expansion)	3 samples: (carbon core wire)

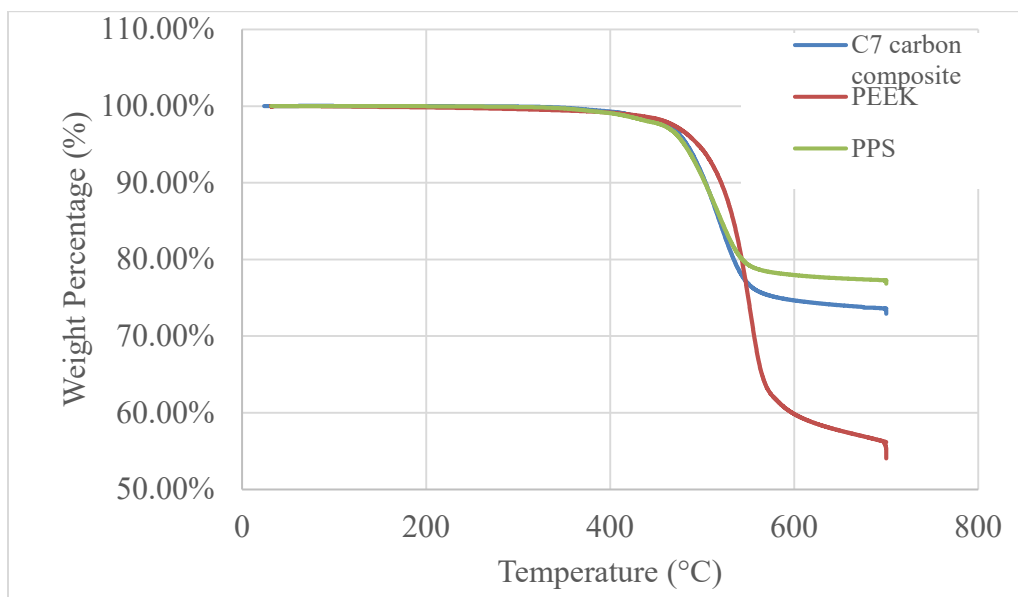

#### 3.1 TGA test results

TGA determines the change in weight relation to change in temperature or time; typically used to determine characteristics of polymer materials to determine degradation temperatures. Samples of each constituent present in the C7 composite core, such as PEEK, PPS, and C7 carbon core were prepared. The samples were continually weighed in the oven of a thermobalance, and the resulting masses were recorded on a computer.

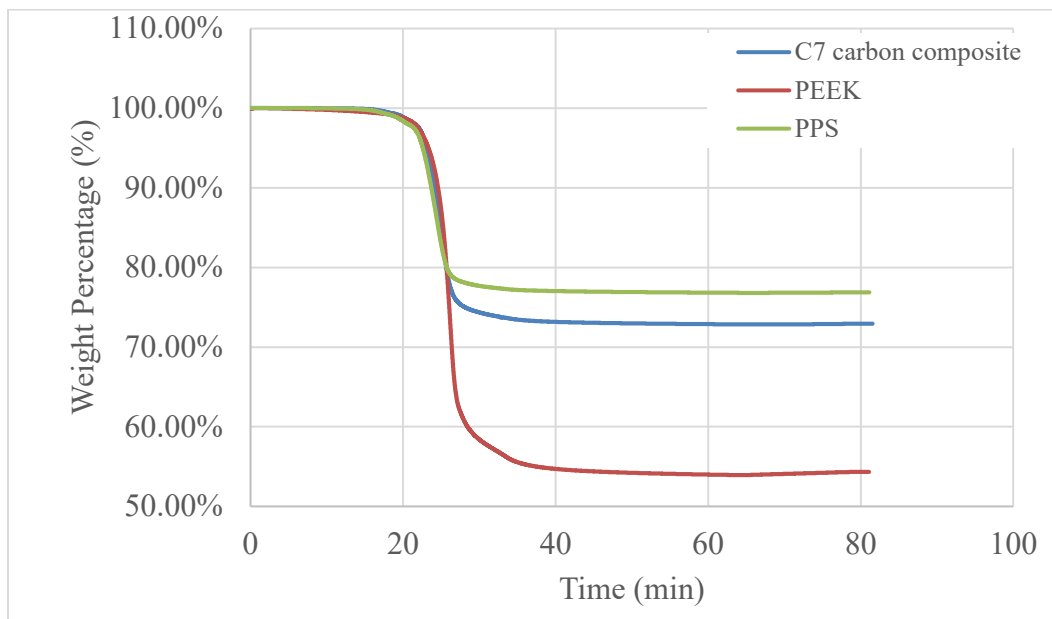

Figure 16 is a TGA thermogram of the C7 composite core, PPS, and PEEK, obtained between 25°C and 700°C, with a rate of warming of 20°C min<sup>-1</sup>, under nitrogen. The main mass loss processes can be distinguished, centered around 500°C. Above 600°C, the mass of the sample had limited changes for PPS and C7 carbon core samples. It can reasonably be assumed that the whole of the polymer matrix has been pyrolyzed. The fraction of charge mass in the PPS composite was estimated at 78%, which corresponds to a fraction of polymer matrix in the total mass of 22%. The body of tests carried out on the C7 carbon composite core sample led to fractions of polymer matrix in the total mass at about 26%. The experimental error was estimated at  $\pm 3\%$ .

Figure 17 is a TGA thermogram of C7 composite core samples obtained between 25°C and 700°C, with a rate of warming of 20°C min<sup>-1</sup>, under air. The main mass loss processes can be distinguished, centered around 550°C. Above 600°C, the mass of the PEEK sample was

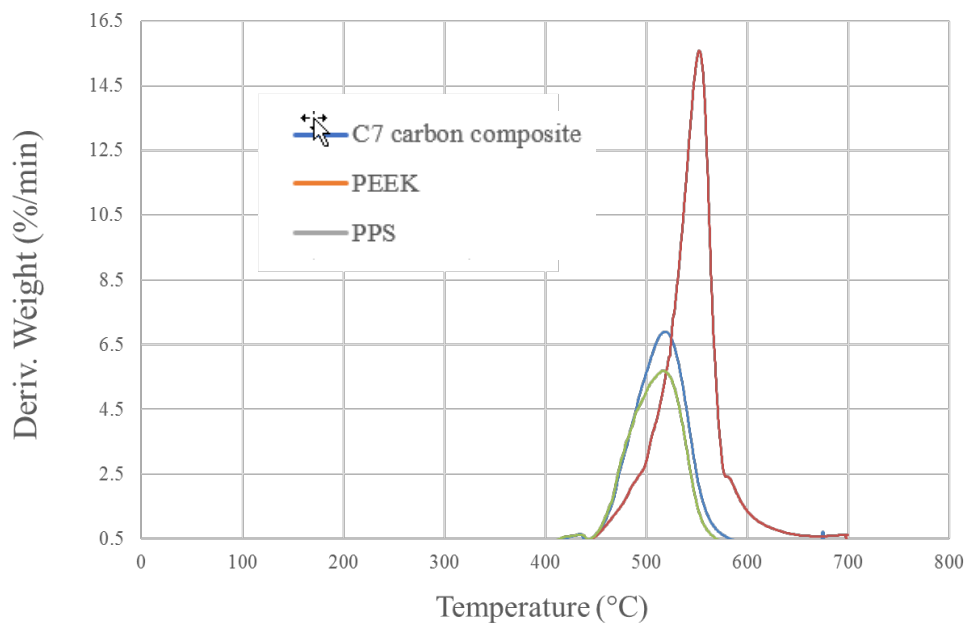

completely combusted, and the C7 carbon composite core and the PPS were not completely combusted after 2 hours at 700C.

**TGA test results Weight Loss-Temperature profile in nitrogen.**

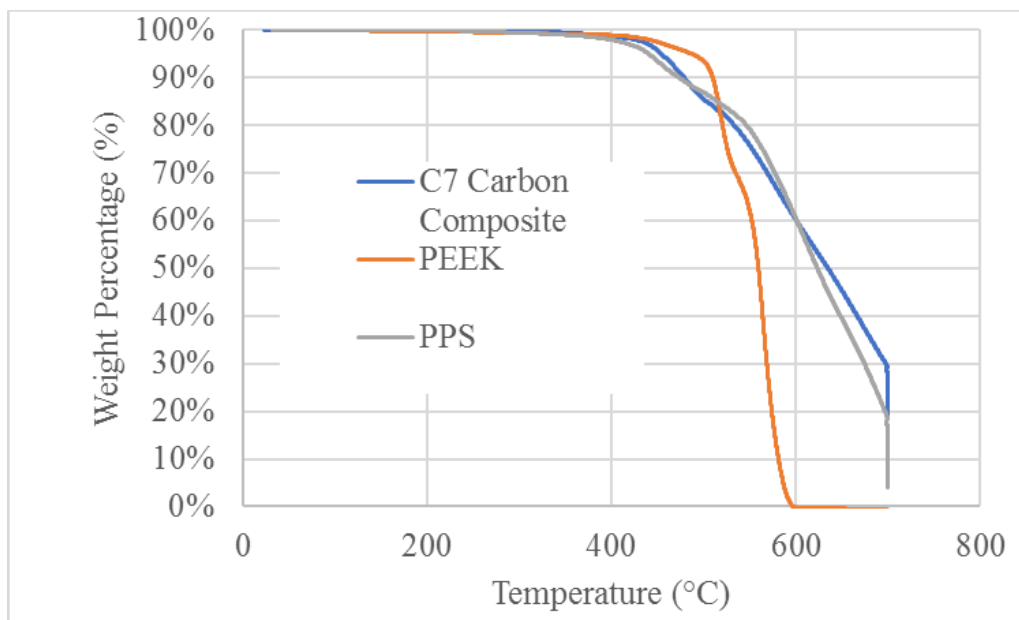

**TGA test results Weight loss-Time history in nitrogen.**

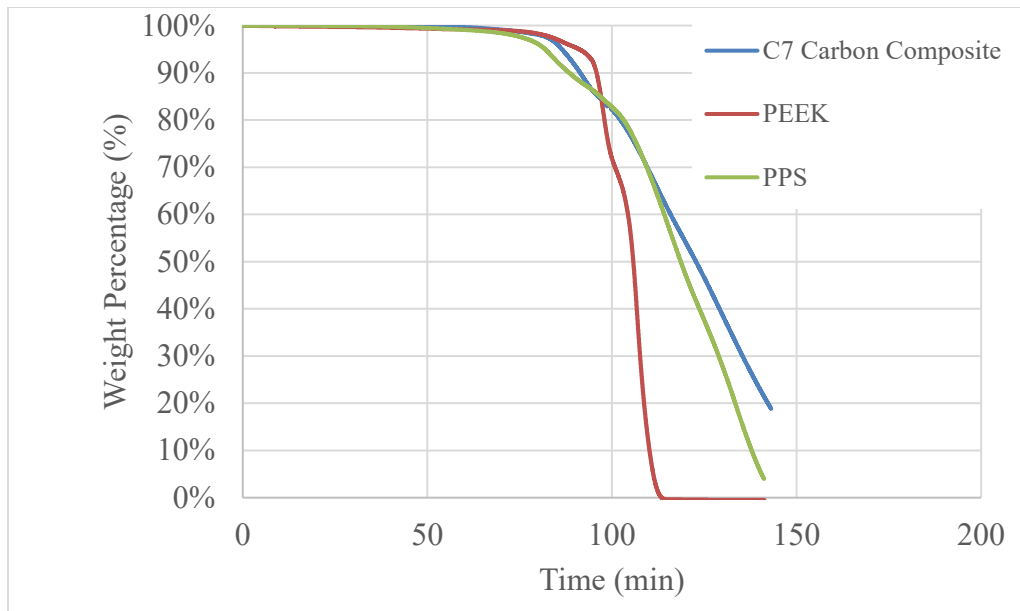

First derivative of TGA test results in nitrogen.

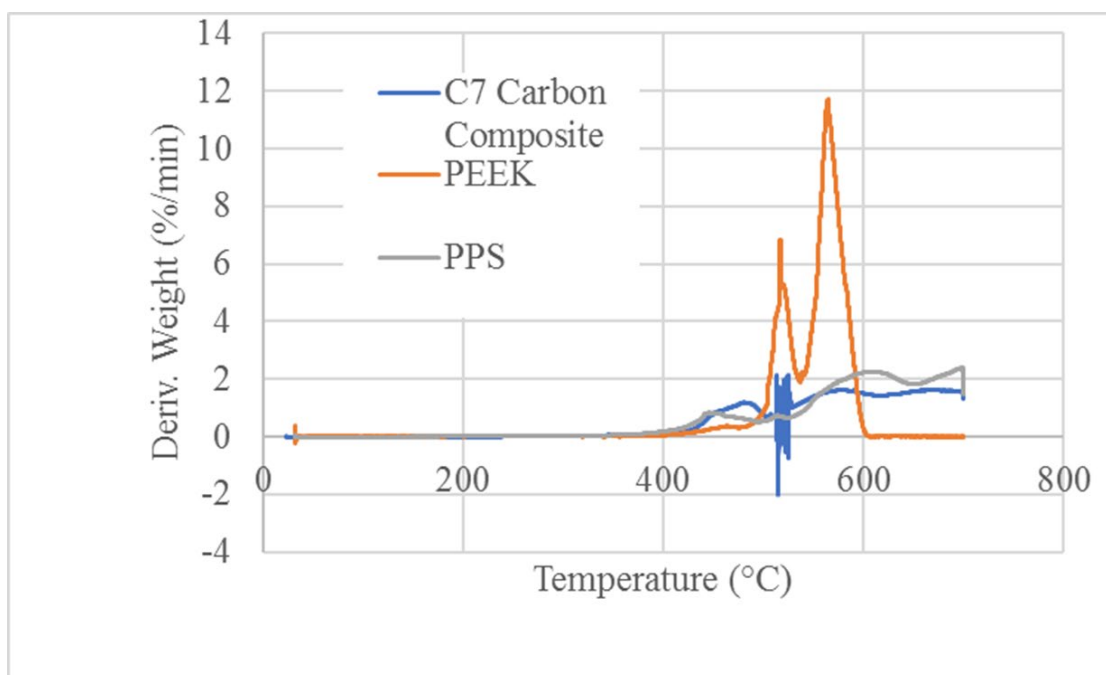

**Figure 16 TGA test results in nitrogen for data up to 700C. The PEEK loses ~45% of its weight and the PPS loses ~22% with the C7 carbon core in between at ~26%. The PEEK loses its volatiles at 555°C and the PPS at 525°C.**

TGA test results Weight Loss-Temperature profile in air

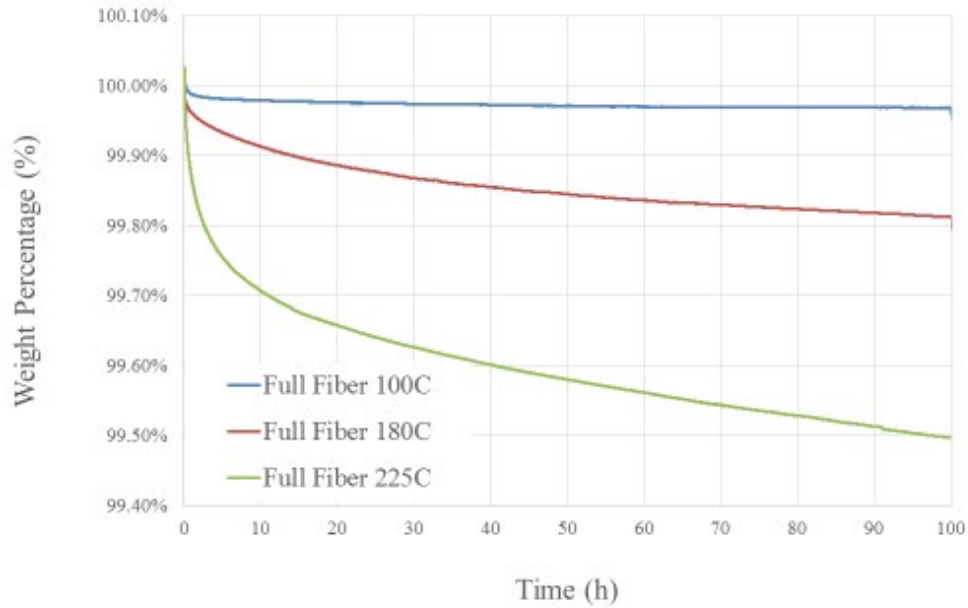

**TGA test results Weight loss-Time history in air**

**First derivative of TGA test results in air**

**Figure 17 TGA test results in air, where the C7 carbon and the PPS were not completely combusted after 2 hours at 700°C. The noisiness of the C7 carbon composite derivative curve might be due to the cylindrical fiber rolling a little bit during combustion.**

The TGA thermal aging study of C7 carbon core sample under 100 hours thermal aging in nitrogen is shown in Figure 18, which shows the changes between 100°C, 180°C and 210°C under nitrogen of the masses of test samples made up from the C7 carbon core. In this case, the whole volume of the C7 composite core samples is subject to the effects of thermolysis alone. Figure 18 shows good thermal stability of the C7 carbon composite core aging under 100°C, and minor change in 180°C up to 0.2% weight loss in contrast to the 225°C thermal aging with 0.5% weight loss at the end of 100 hours thermal aging.

**Figure 18 TGA thermal aging test results in nitrogen, which shows the variations in the mass of C7 carbon core samples among 100°C, 180°C, and 210°C under nitrogen.**

### 3.2 DMA testing results

#### Principle of DMA

Dynamic mechanical properties refer to the response of a material as it is subjected to a periodic force. These properties may be expressed in terms of a dynamic modulus, a dynamic loss modulus, and a mechanical damping term. Typical values of dynamic moduli for polymers range from  $10^6$ - $10^{12}$  dyne/cm<sup>2</sup> ( $0.1$ - $10^5$  MPa) depending upon the type of polymer, temperature, and frequency.

For an applied stress varying sinusoidally with time, a viscoelastic material will also respond with a sinusoidal strain for low amplitudes of stress. The sinusoidal variation in time is usually described as a rate specified by the frequency ( $f = \text{Hz}$ ;  $\omega = \text{rad/sec}$ ). The strain of a viscoelastic body is out of phase with the stress applied, by the phase angle,  $\delta$ . This phase lag is due to the excess time necessary for molecular motions and relaxations to occur. Dynamic stress,  $\sigma$ , and strain,  $\epsilon$ , given as:

$$(1) \sigma = \sigma_o \sin(\omega t + \delta)$$

$$(2) \epsilon = \epsilon_o \sin(\omega t)$$

where  $\omega$  is the angular frequency. Using this notation, stress can be divided into an “in-phase” component ( $\sigma_o \cos\delta$ ) and an “out-of-phase” component ( $\sigma_o \sin\delta$ ) and rewritten as,

$$(3) \sigma = \sigma_o \sin(\omega t) \cos \delta + \sigma_o \cos(\omega t) \sin \delta.$$

Dividing stress by strain to yield a modulus and using the symbols  $E'$  and  $E''$  for the in-phase (real) and out-of-phase (imaginary) moduli yields:

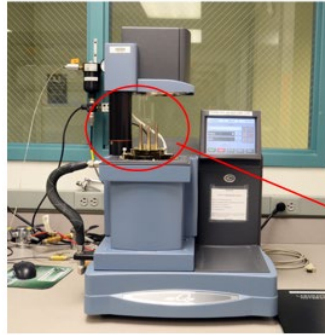

$$(4) \sigma = \epsilon_o E' \sin(\omega t) + \epsilon_o E'' \cos(\omega t)$$

$$(5) \quad E' = \frac{\sigma_o}{\epsilon_o} \cos \delta \qquad E'' = \frac{\sigma_o}{\epsilon_o} \sin \delta$$

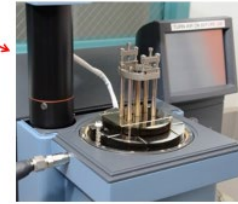

$$(6) \epsilon = \epsilon_o \exp(i\omega t), \quad \sigma = \sigma_o \exp(\omega t + \delta) i$$

$$(7) \quad E^* = \frac{\sigma}{\epsilon} = \frac{\sigma_o}{\epsilon_o} e^{i\delta} = \frac{\sigma_o}{\epsilon_o} (\cos \delta + i \sin \delta) = E' + iE''$$

#### DMA Q800 Tester Set-up

DMA is a technique used to characterize materials, specifically polymers, such as Tg. It applies a displacement to a sample and measures the mechanical response of the bulk material in a controlled temperature environment.

Equation (7) shows that the complex modulus obtained from a dynamic mechanical test consists of “real” and “imaginary” parts. The real (storage) part describes the ability of the material to store potential energy and release it upon deformation. The imaginary (loss) portion is associated with energy dissipation in the form of heat upon deformation. The above equation is rewritten for shear modulus as,

$$(8) \quad G^* = G' + iG''$$

where  $G'$  is the storage modulus and  $G''$  is the loss modulus. The phase angle  $\delta$  is given by

$$(9) \quad \tan \delta = \frac{G''}{G'}$$

The storage modulus is often associated with “stiffness” of a material and is related to the Young’s modulus,  $E$ . The dynamic loss modulus is often associated with “internal friction” and is sensitive to different kinds of molecular motions, relaxation processes, transitions, morphology and other structural heterogeneities. Thus, the dynamic properties provide information at the molecular level to understanding the polymer mechanical behavior.

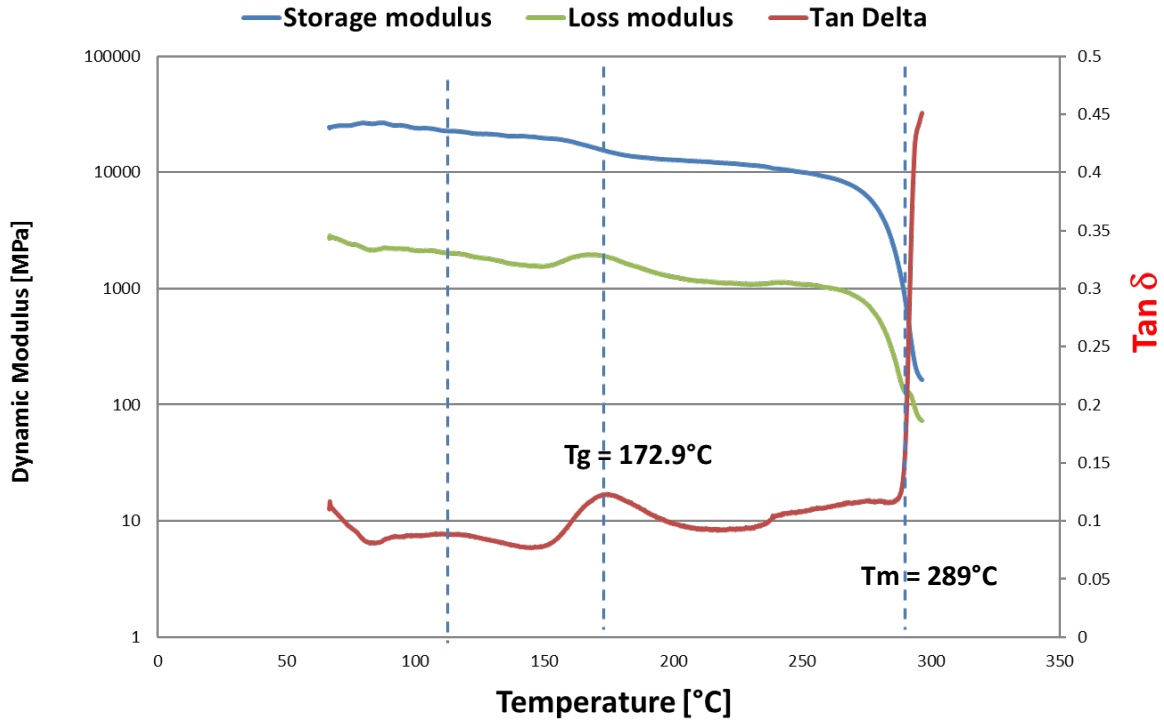

The  $T_g$  is seen as a large drop (a decade or more) in the storage modulus when viewed on a log scale against a linear temperature scale, shown in Figures 2-3. A concurrent peak in the  $\tan \delta$  is also seen. The value reported as the  $T_g$  varies with industry with the onset of the  $E'$  drop, the peak of the  $\tan \delta$ , and the peak of the  $E''$  curve being the most commonly used.

The performed DMA test results on the baseline C7 carbon core samples and the associated  $T_g$  values are provided in Figures 19-28. The storage modulus  $G'$ , loss modulus  $G''$ , and  $\tan \delta$  were measured at a frequency of 1 Hz, where the DMA test parameters are provided in the associated figures per each DMA test. DMA trace on thermal cycles aging C7 carbon core sample received from EPRI is shown on Figures 29-30.

There are two  $T_g$  of C7 carbon composite core samples observed from DMA technique, at 90°C and 170°C regions; and the melting temperature is around 290°C. Which seems to be consistent to  $T_g$  of 89°C and 150°C for PPS and PEEK, respectively, shown in Table 1. Apparently these  $T_g$  of 90°C are lower than 180°C of C7 conductor operation temperature. And the C7 carbon composite core melting temperature is consistent with that of PPS at 275°C shown in Figure 6. Nevertheless, based on Table 3, the recommended heavy and long-term operation for PPS and PEEK are 85°C and 138°C, respectively.

Comparison of EPRI thermal cycle aging C7 carbon core samples DMA test results and baseline C7 carbon core sample DMA test results was shown in Figure 30. Which shows decrease in storage and loss modulus from aging C7 carbon core sample compared to that of baseline C7 carbon core sample; and thermal cycling aging sample also shows lower damping than that of the baseline sample. The aging sample DMA test result shows increase in  $T_g$  compared to that of baseline sample.

The details of C7 core samples DMA test results are provided below.

The aging sample DMA test result shows increase in Tg compared to that of baseline sample.**

### 3.3 TMA testing results

#### Principles of TMA

A dilatometer is used to determine the linear thermal expansion of a solid as a function of temperature. Unlike the classical methods in which the experimental setup is kept as free of forces as possible, in the thermomechanical analysis, a constant, usually small load acts on the specimen. The measured expansion of the specimen can be used to determine the coefficient of linear thermal expansion  $\alpha$ .

#### TMA Q400 Tester Set-up

Thermomechanical Analysis (TMA), is a technique that measures changes in sample size as a function of temperature, time and load.

The 1st heating phase yields information about the actual state of the specimen, including its thermal and mechanical history. When thermoplastics soften, especially above the glass transition, orientations and stresses may relax, as a result of which post-crystallization and recrystallization processes may occur. On the other hand, the specimen may deform under the applied test load. To determine the coefficient of expansion as a material characteristic, the material must not undergo irreversible changes, such as post-crystallization, post-polymerization, relaxation of orientation or internal stress and so forth during a 2nd heating phase that has followed controlled cooling. Also, the anisotropy of the sample part must be taken into account.

The coefficient of linear thermal expansion can serve as a material characteristic only where material behavior is reversible. The coefficient of thermal expansion ( $1 \times 10^{-6}/^{\circ}\text{C}$ ) comparison of different materials is shown to the right.

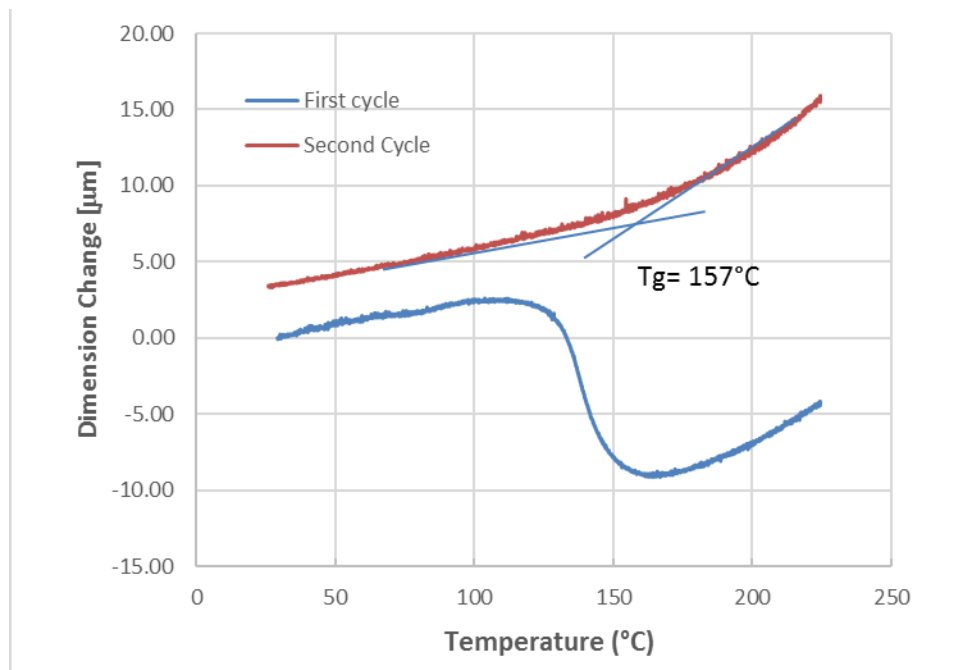

• 1350 Aluminum (all tempers)	23.0
• Aluminum Alloys (all)	23.0
• Copper	16.0
• Steel	11.5
• Metal Matrix Composite (3M)	6.3
• Polymer Composite	1.7

The temperature-dependent change of length is the progressive change of length expressed regarding the initial length/reference length  $l_0$ . It is a relative measure of the linear expansion, which always has a value of 0 at the start of the trial at the reference temperature  $T_0$ . The differential (or local) coefficient of linear thermal expansion  $\alpha(T)$  is derived as follows:

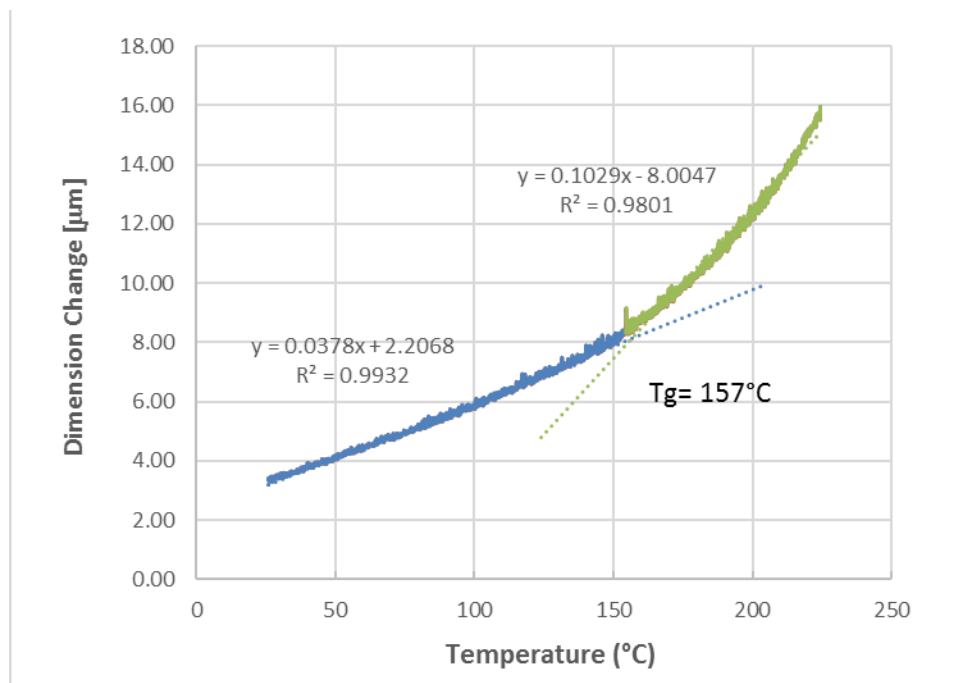

$$\alpha(T) = \frac{1}{l_0} \cdot \frac{dl_{th}}{dT} \quad \left[ \frac{\mu\text{m}}{\text{m } ^{\circ}\text{C}} \right]$$

The values may assume the dimensions  $[10^{-6} \text{ } ^{\circ}\text{C}^{-1}]$ .

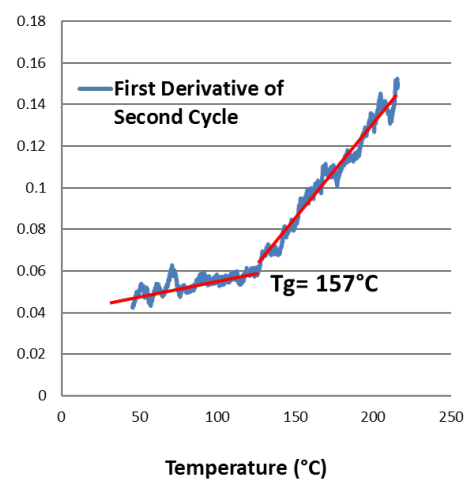

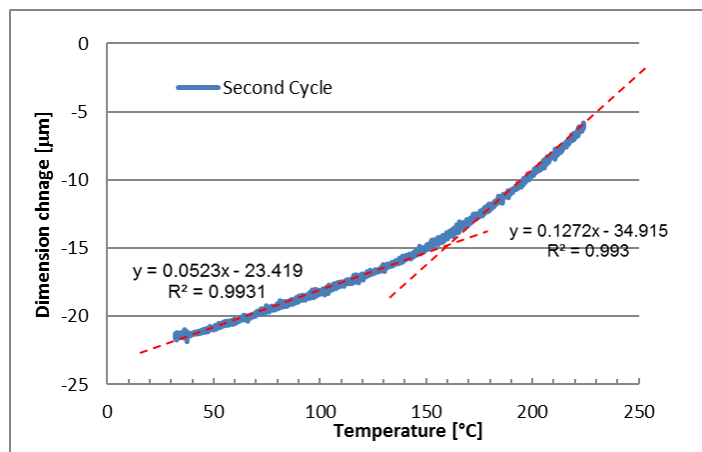

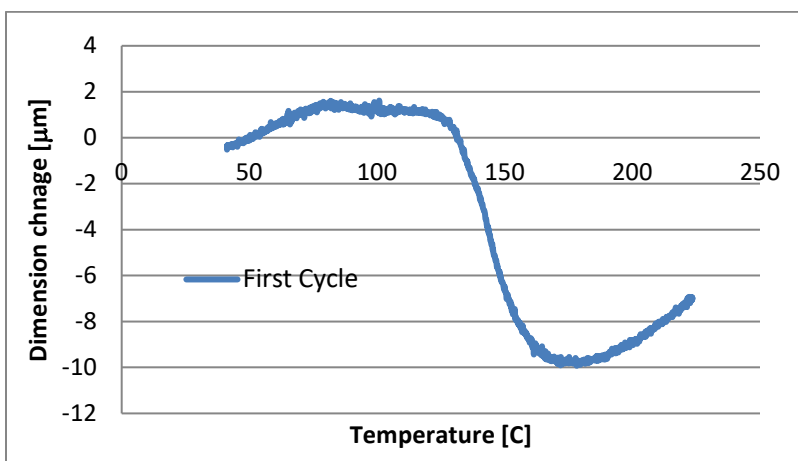

The  $T_g$  evaluated from TMA technique is around  $157^{\circ}\text{C}$  to  $170^{\circ}\text{C}$  for the baseline C7 core and about  $193^{\circ}\text{C}$  for the thermal cycle aged C7 core sample. However, the linear thermal expansion coefficient for the post- $T_g$  region is around  $3.23\text{E-}6$  to  $6.49\text{E-}6/^{\circ}\text{C}$ , which is about 2-4 times higher than  $1.7\text{E-}6/^{\circ}\text{C}$  for the typical polymer composite.

## 4 THERMAL AGING CHARACTERIZATION USING 3-POINT BENDING TEST

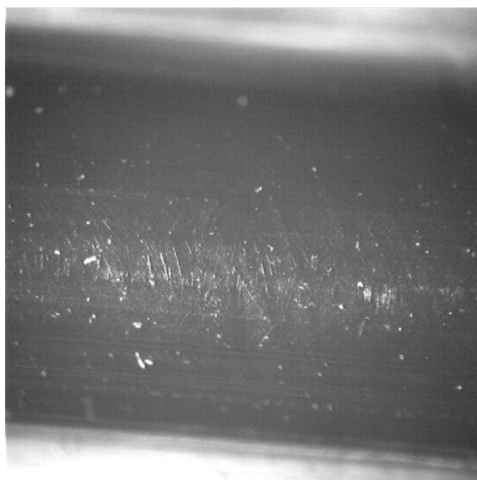

The thermal aging experiments were carried out on C7 carbon composite core sample with dimension of  $\phi 3.45$  mm x 100 mm in an oven the air, at 180°C for 100, 500, and 1000 hours; and at 225°C for 100 hours. The thermal aging characterizations were performed on baseline and thermally aged C7 composite core samples using 3-point bending test; the test results and the associated aging characteristics are discussion in this section.

Techniques	Characteristics	Planned number of samples
Microscopy analysis	Presence of cracks Homogeneity of the material	3 samples, rods $\phi 3.45$ x 100 mm coming out of ageing program + new one.
3-point flexural ASTM D790	Maximum deflection and failure load of the sample during the test	3 samples per (time-temperature) rods $\phi 3.45$ x 100 mm

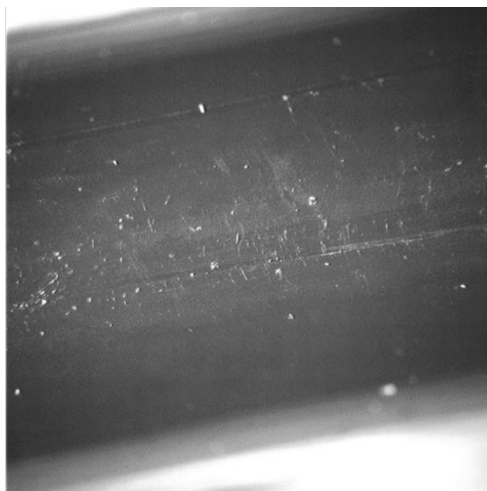

The aging C7 core samples were compared to baseline C7 core samples, shown in Figure 38; no apparent surface crack or damage were observed.

## 4.1 3-point Bending Test Results

General observations from C7 core sample 3-point test results are stated below.

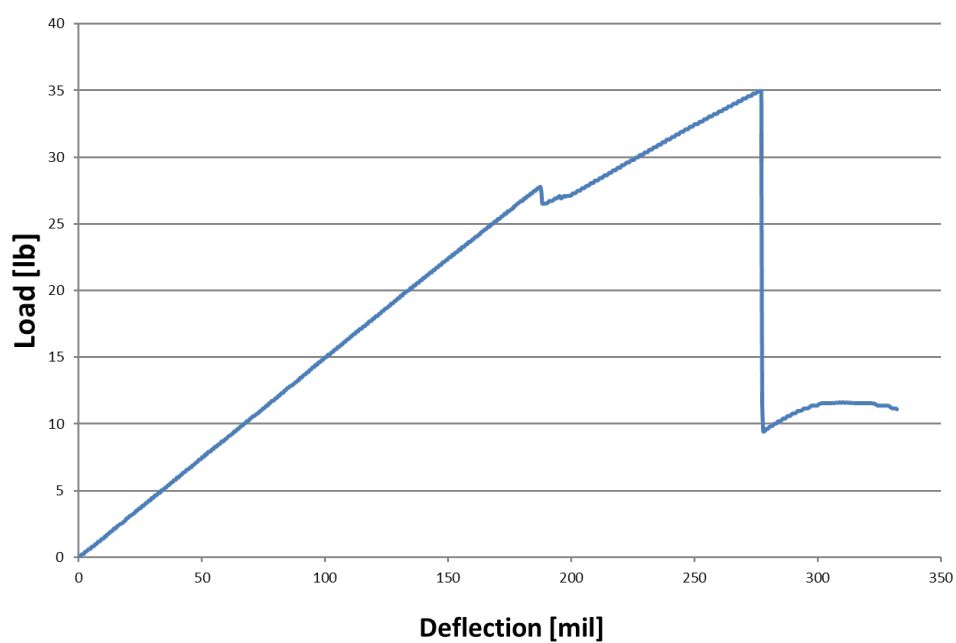

- Baseline C7 carbon core samples failed within loading ranges of 30 - 35 lb. and deflection ranges of 0.24 – 0.38 inch. The pop-in occurred around 15 lb. and 27.5 lb.
- Thermally aged sample of 180°C-500 hours failed at 33.9 lb. at 0.297-inch deflection.
- Thermally aged sample of 180°C-1000 hours failed at 46.4 lb. at 0.455-inch deflection.
- Thermally aged sample of 225°C-100 hours failed at 40.2 lb. at 0.406-inch deflection.
- Baseline maximum stress is around 119 ksi to 139 ksi, the corresponding maximum strain range is around 0.83% to 1.31%.
- Maximum stress range of the thermal aging samples is around 133 ksi to 184 ksi, and the corresponding maximum strain at failure is around 1.01% to 1.52% strain ranges.
- For EPRI thermal cycling aged samples, the maximum stress range is around 131 ksi to 153 ksi, and the corresponding maximum strain at failure is around 1.062% to 1.256%.
- The Young's modulus appeared to be reduced for thermal aging C7 core samples compared to that of baseline C7 core samples.
- The average Young's modulus of tested C7 core materials is around 8.5 msi, which is about 1/3 value compared to that of steel.
- C7 core tested data of O-temp conductor has higher deflection than that of Zr-Al conductor.

The details of the 3-point bending test results are shown in Figures 39-57.

## 5 THERMAL AGING CHARACTERIZATION USING TENSILE TEST

### 5.1 Pilot tensile test and sample grip design

The C7 sample with 4-inch gage section and 2-inch hydraulic grip section was designed and used for pilot tensile testing. The maximum tensile load reached upon failure is around 2000 lb. The C7 composite core sample was failed at grip section, as shown in Figure 58; and apparently PEEK layer fracture and delamination are the root cause.

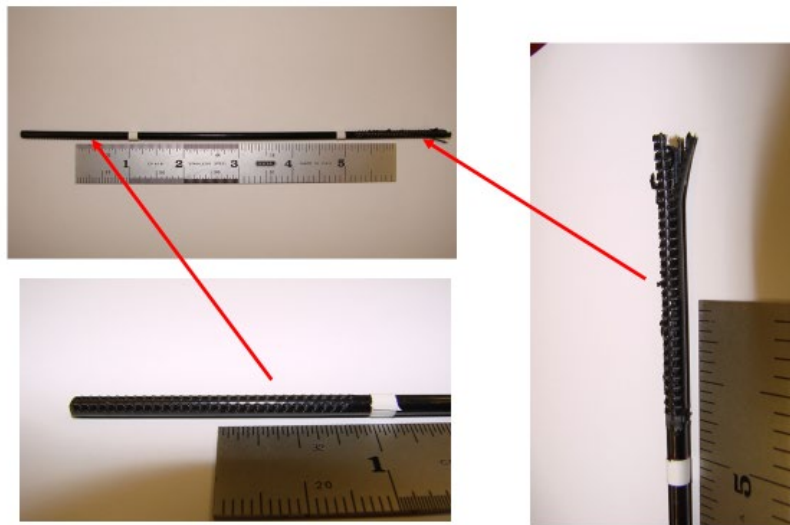

Figure 58 C7 core tensile testing using hydraulic grip clamps of 2-inch in length.

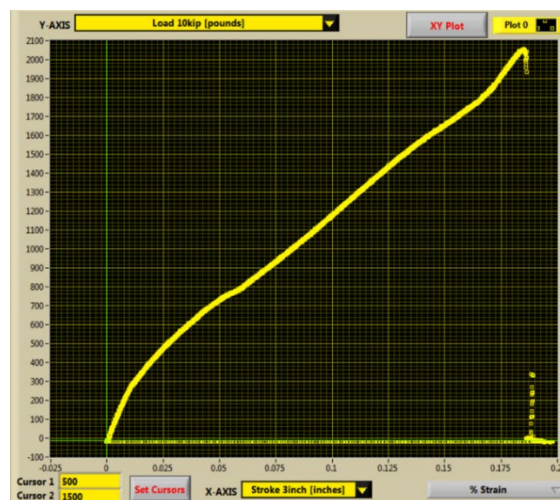

Figure 59 C7 core pilot tensile test load-stroke history.

A series of grip modifications and pilot testing, demonstrated in Figures 61-63, were designed and performed to improve the C7 core sample's grip capacity under tensile test; and to ensure C7 core sample will fail at gage section instead of at grip region, as outlined below.

- Special grip design to ensure sufficient friction strength during tensile testing
  - Grip plate dimension, and grove depth
  - Copper bushing insert dimension to provide sufficient protection to the C7 rods
  - Bolt sizes to ensure sufficient compressive stress on grip plates
  - Interface bonding adhesive to increase interface shear resistance
- Tensile testing under different loading rates;
  - 0.0003 in/sec, 0.003 in/sec, 0.03 in/sec, and 0.3 in/sec
- C7 fracture initiation site
- C7 failure profile considerations
  - Catastrophic damage mechanism, C7 rod upon failure completely disintegrated into fibrous form under medium or low loading rate; while at very high loading rate C7 fail at much lower load compared to that of low or medium loading rate and C7 rod failed in a brittle failure mode with C7 core sample cross-section nearly intact.
- C7 Young's Modulus and its comparison to steel
  - In general, C7 has much lower E, (8-10 msi), it's about 30% of that of steel (29 msi) shown in Figure 60; which means large deformation/displacement under load would be experienced by C7 core wire compared to that of steel deformation.

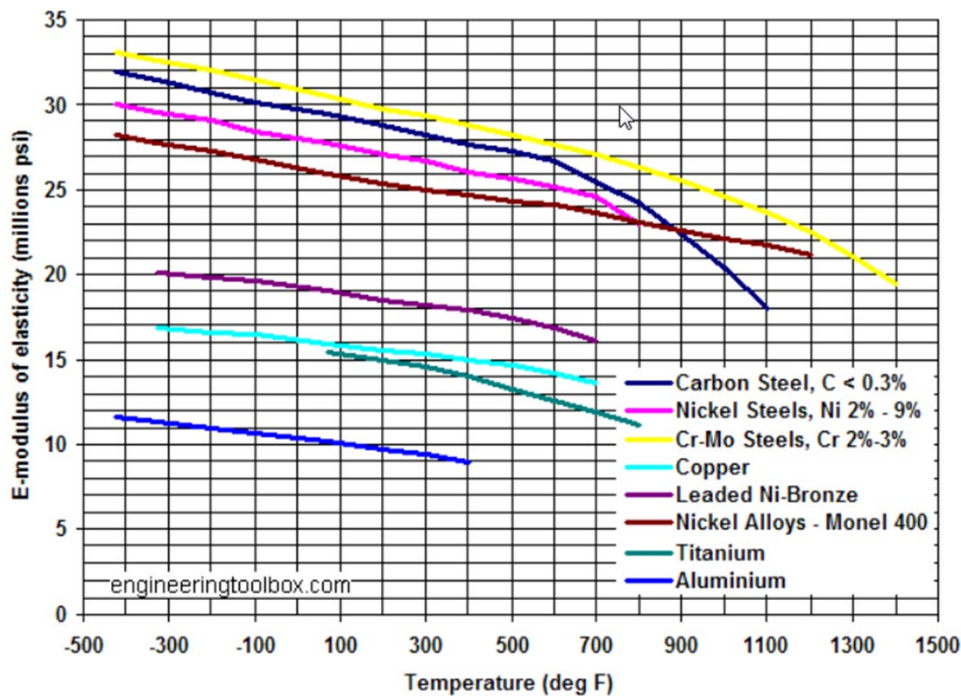

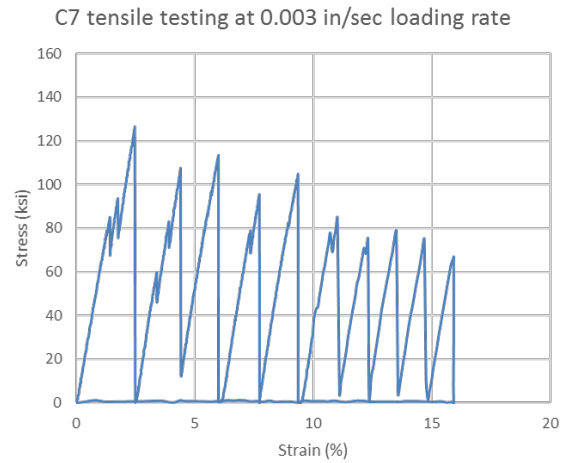

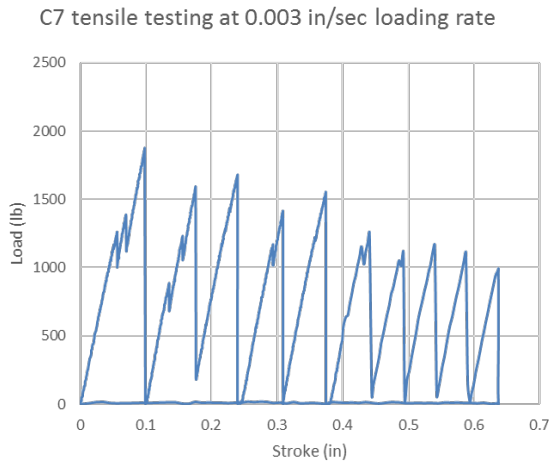

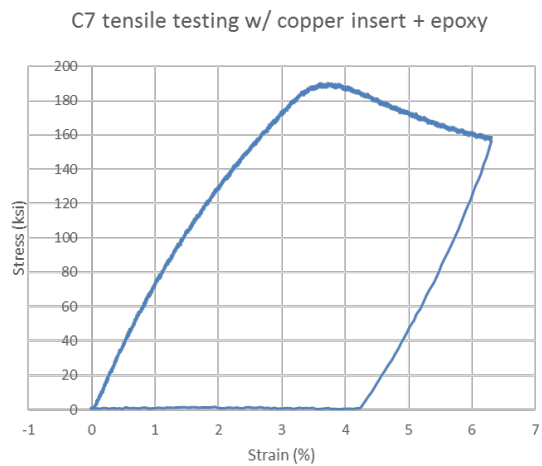

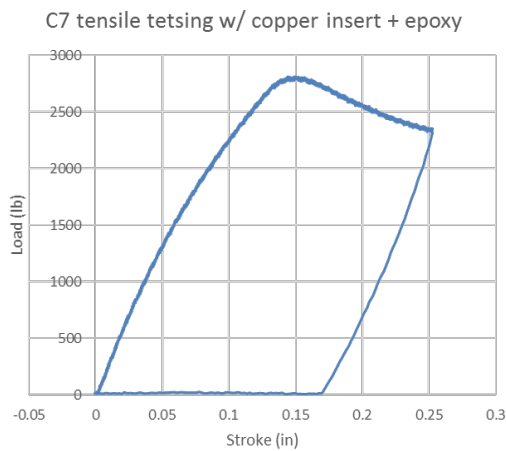

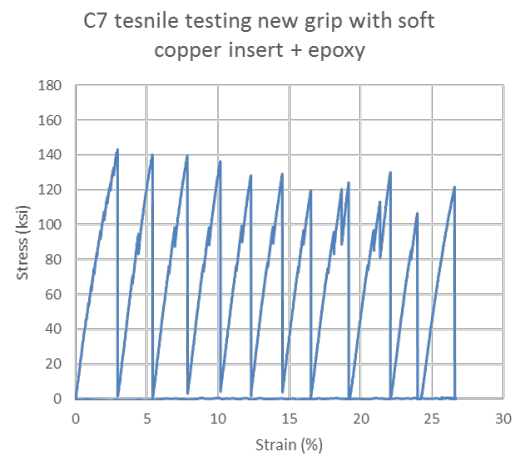

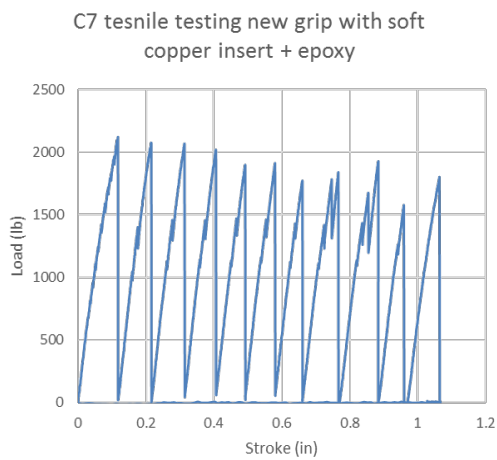

Figure 60 Metallic Materials Tensile Testing General Trends.

**Figure 61 C7 core tensile test using new grip design with brass insert shows grip slip.**

**Figure 62 Tensile testing using grip w/ thin hard copper insert + epoxy shows grip slip.**

**Figure 63 Tensile testing using new grip with thick soft copper insert + epoxy shows slip.**

After a series of pilot testing on the grip designs; the soft copper insert with sufficient grip length of 5.75-inch was adopted for the sample grip. The detail of the final grip design is shown in Figure 64. The C7 composite core samples tensile test results are detailed in Figures 64-89.

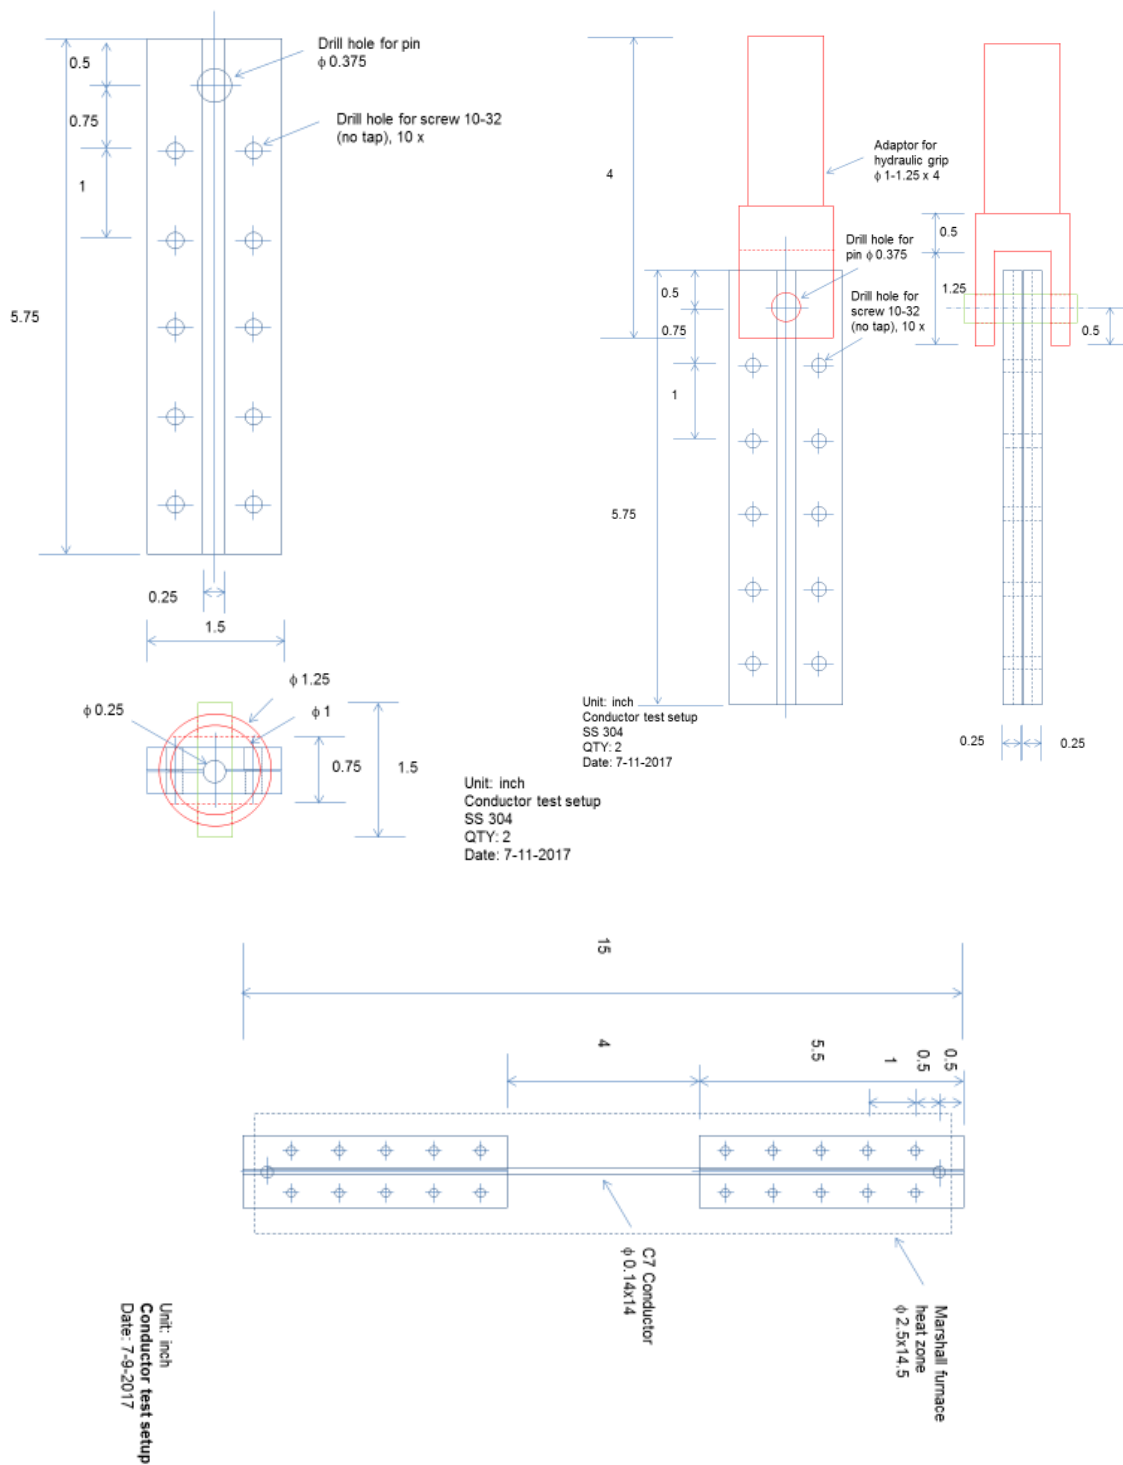

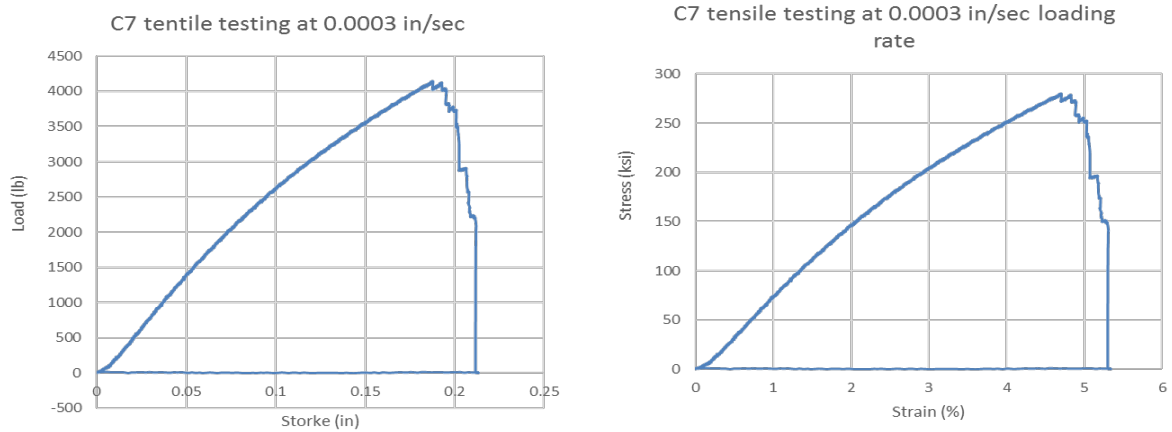

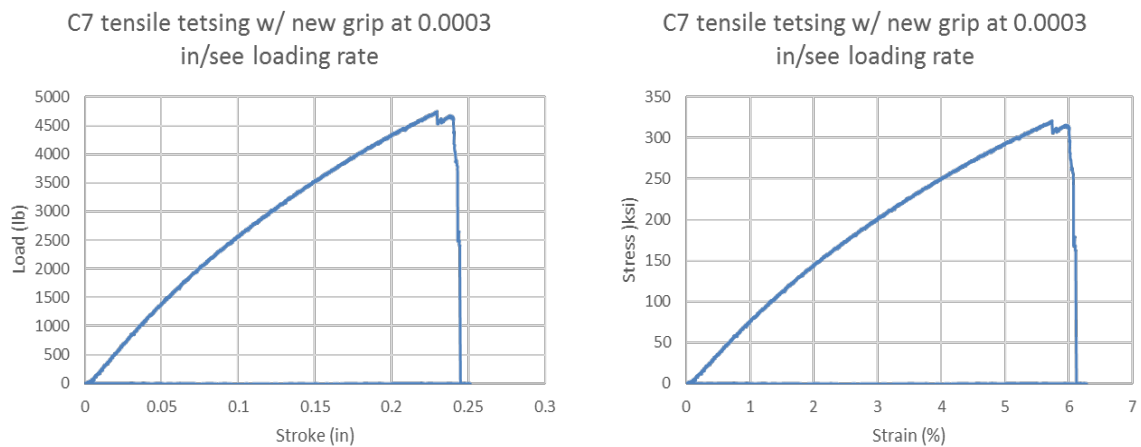

Figure 64 Final grip design for C7 core sample tensile testing.

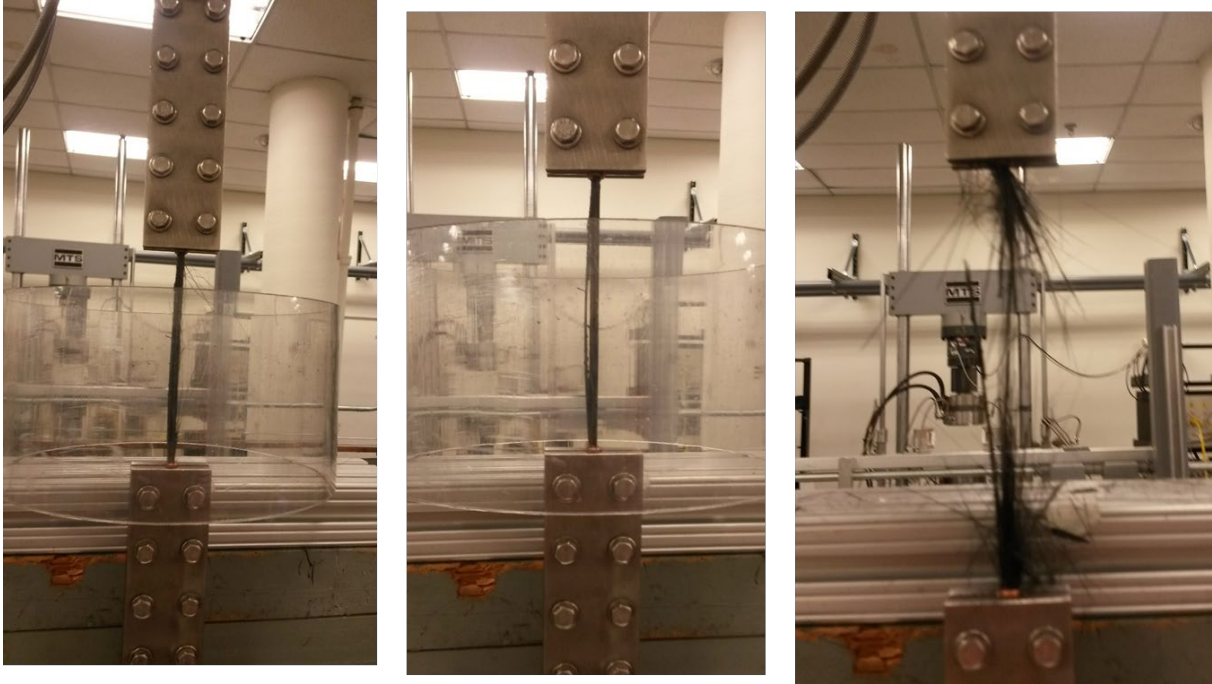

## 5.2 C7 composite core sample tensile test results at room temperature

Based on the new grip design a series of loading rate dependent tensile tests were performed as detailed below.

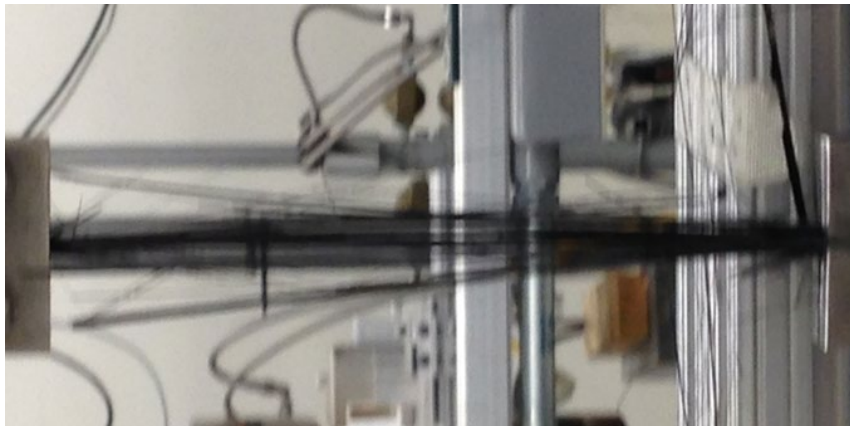

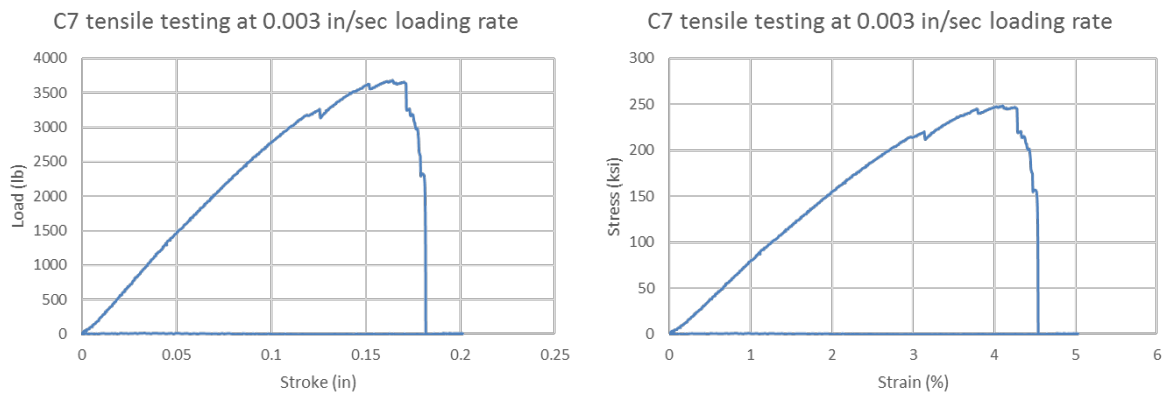

**Figure 65 C7 core tensile testing at 0.0003 in/sec loading rate.**

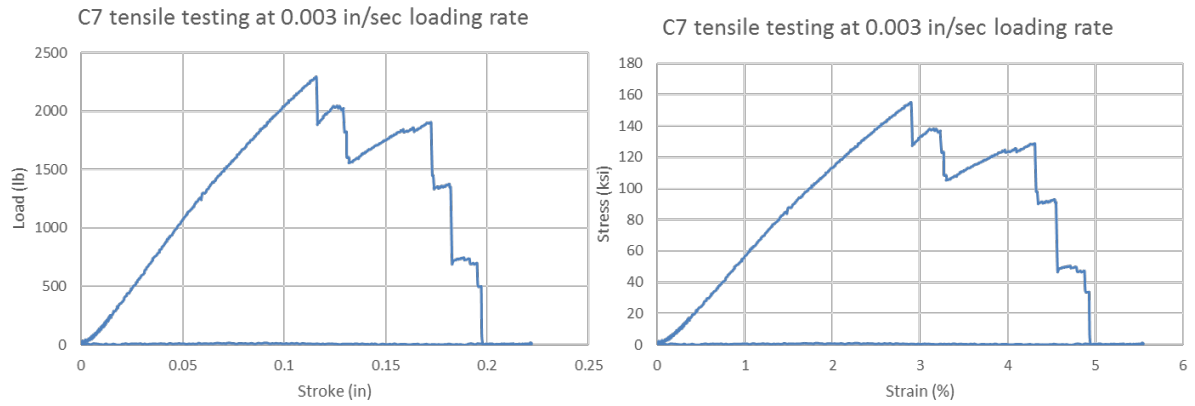

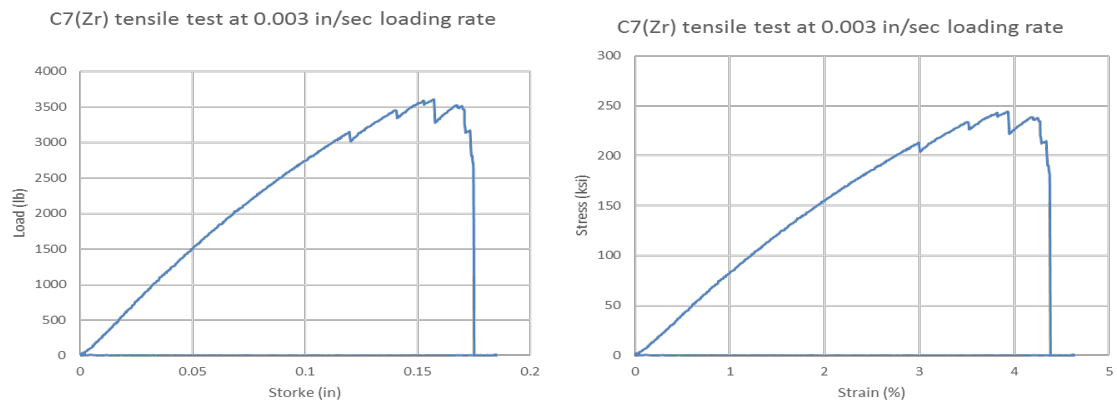

**Figure 66 C7 core tensile testing failure evolutions, from left to right, at 0.0003 in/sec loading rate.**

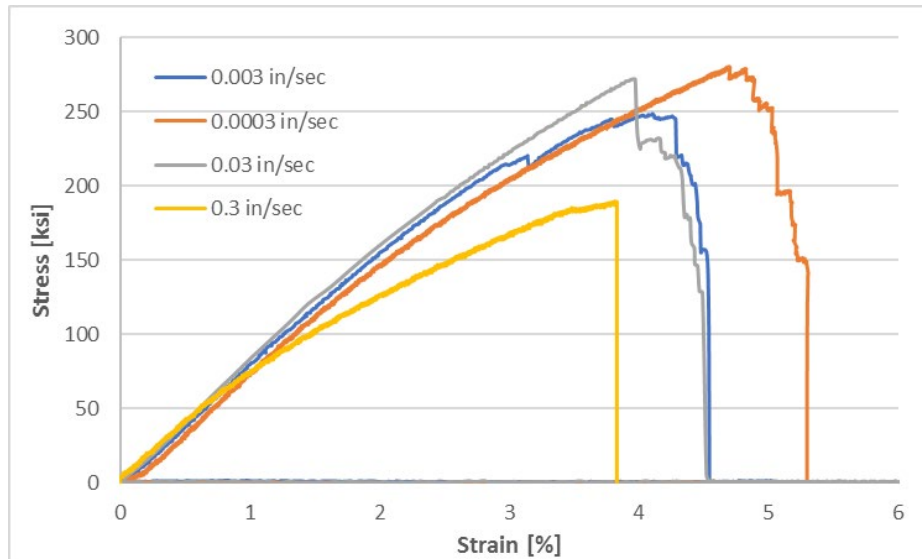

**Figure 72 C7 core tensile testing at 0.3 in/sec loading rate, where fast brittle fracture at failure site was observed w/o carbon fibers and PPS matrix disintegration in contrast to significant C7 core carbon fibers/PPS matrix disintegration revealed from other lower loading rate tensile tests.**

**Figure 73 C7 core tensile testing at 0.003 in/s loading rate, for baseline and EPRI thermal cycle aged samples. Aged EPRI C7 core from Zr-Al conductor has lower ductility compared to aged EPRI C7 core from O-temp conductor.**

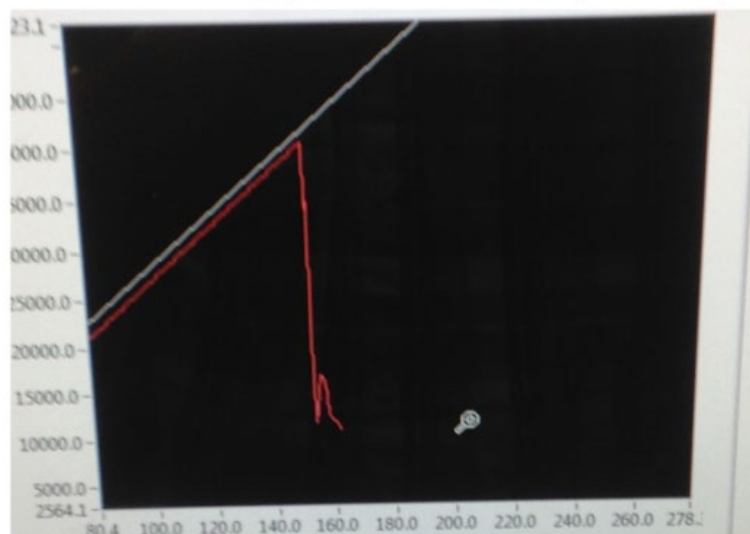

**Figure 74 Comparison of baseline C7 core tensile testing at different loading rates, which show significant ductility reduction at higher loading rate.**

### **Southwire tensile testing on Drake C7 Overhead Conductor**

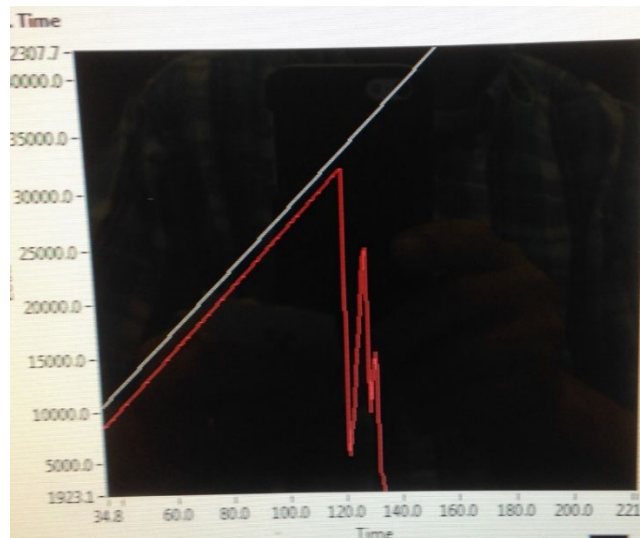

The Southwire tensile test of Drake C7 overhead conductor with O-temp aluminum conductor has a failure capacity of 40K lb, shown in the red trace in Figure 75. Where, the initial residual strength is at 10K lb from the aluminum conductor upon C7 core failure. Thus, the net force capacity carried by 7 C7 core wires is  $40K - 10K = 30K$  lb; each C7 wire strength  $= 30K / 7 = 4250$  lb, which is consistent with that from ORNL C7 core tensile test result.

The Southwire tensile test of Drake C7 overhead conductor with Zr-Al conductor has a failure capacity of 45K lb. Where, the initial residual strength is at 15K lb from the Zr-Al conductor upon C7 core failure. Thus, the net force capacity carried by 7 C7 core wires is  $45K - 15K = 30K$  lb; each C7 wire strength is  $30 / 7 = 4280$  lb.

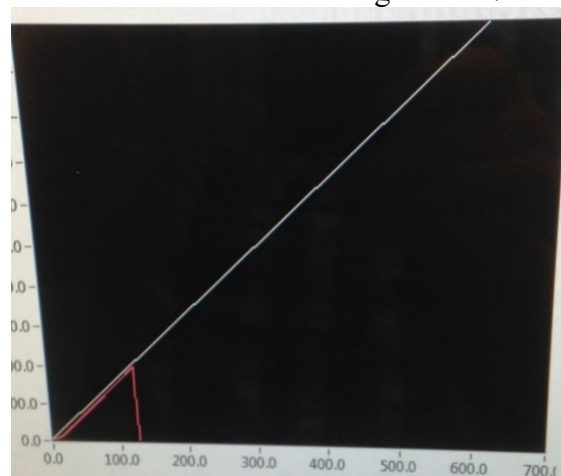

**Figure 75 C7-O-temp conductor splice testing, and C7 conductor failed at 40K lb.**

Southwire tensile test performed on C7 overhead conductor with O-temp aluminum conductor and with a dead-end connector served a C7 conductor grip end, shows about 32K lb. tensile capacity with 5.8 K lb. residual strength, shown in Figure 76. Which is about 8K lb. load reduction in C7 conductor tensile capacity compared to that shown in Figure 75. The estimate C7 core wire strength is about 3700lb each. Which is about 600 lb lower than that of C7 conductor test w/o dead-end connector. This could be interrelated as C7 core wire damage through dead-end connector crimp forming mechanism. Furthermore, postmortem examination also confirmed that the C7 overhead conductor failure site is within the dead-end connector region.

**Figure 76 C7-O-temp Drake conductor tensile testing, end grip equipped with the Dead-end splice, conductor failed at 32K lb. and located inside the Dead-end splice.**

Southwire tensile test performed on C7 overhead conductor with Zr-Al conductor and with a dead-end connector, shows 40K lb. tensile capacity shown in Figure 77, about 5K lb. load reduction compared to that of test sample w/o dead-end type grip; and the test trace showed a 10.8 K lb. residual strength. The estimated tensile strength for C7 core wire is 4,170 lb. each.

**Figure 77 C7 Zr-Al Drake conductor tensile testing, with Dead-end grip; conductor failed at 40K lb. and located inside the Dead-end splice.**

### 5.3 High temperature C7 carbon composite core tensile tests

The high temperature C7 core sample tensile test set-up is shown Figure 78. There are two C7 core sample sizes used in the high temperature tensile testing, which are 15-inch and 27-inch in length, where the corresponding sample grips are located within the furnace and out of furnace, respectively.

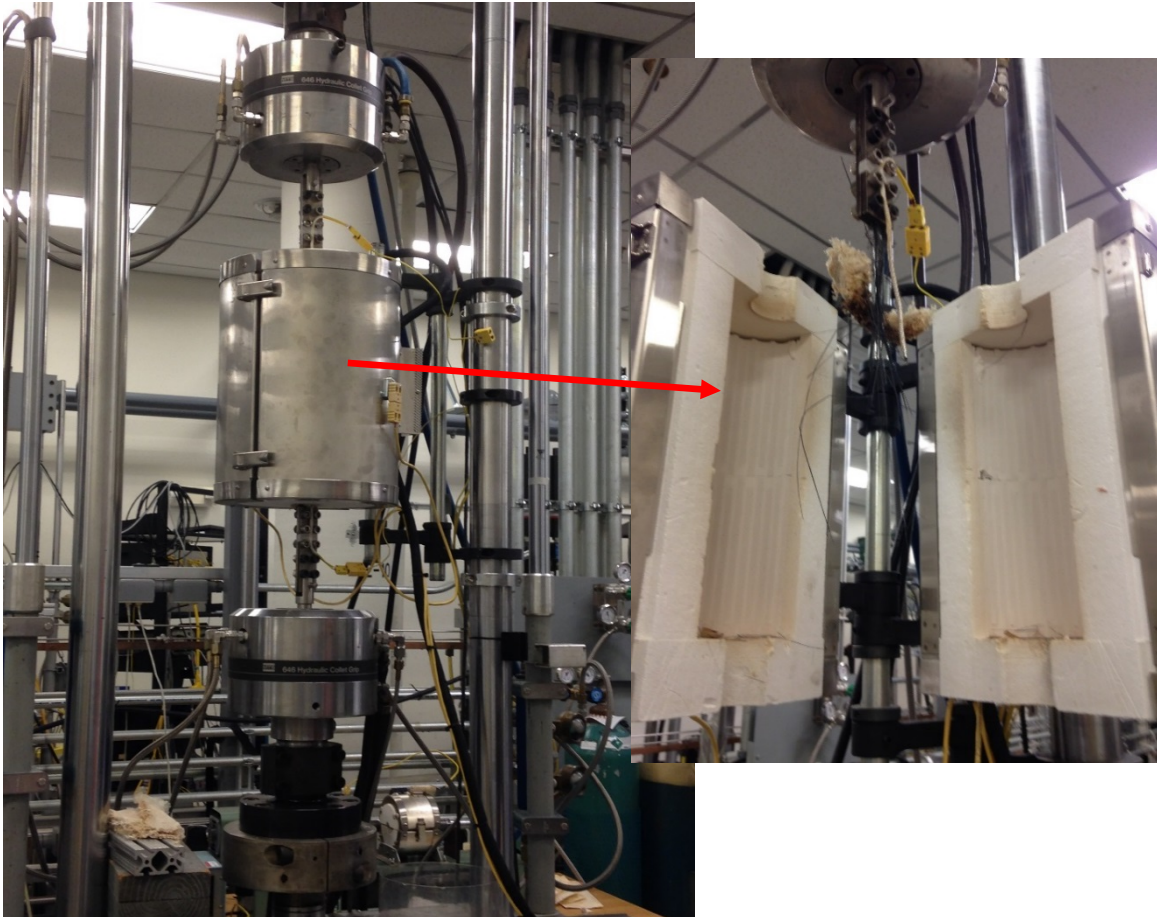

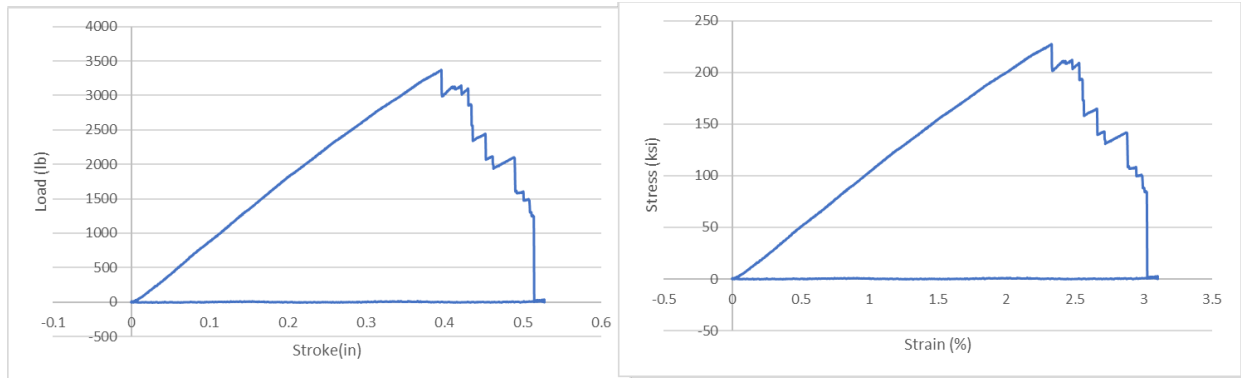

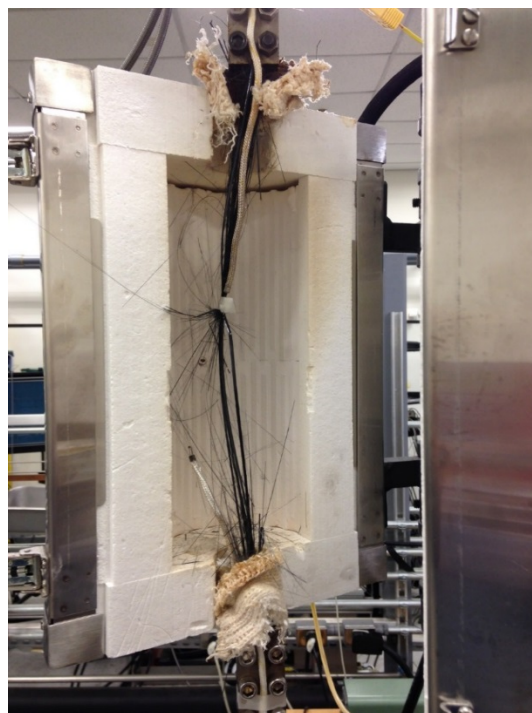

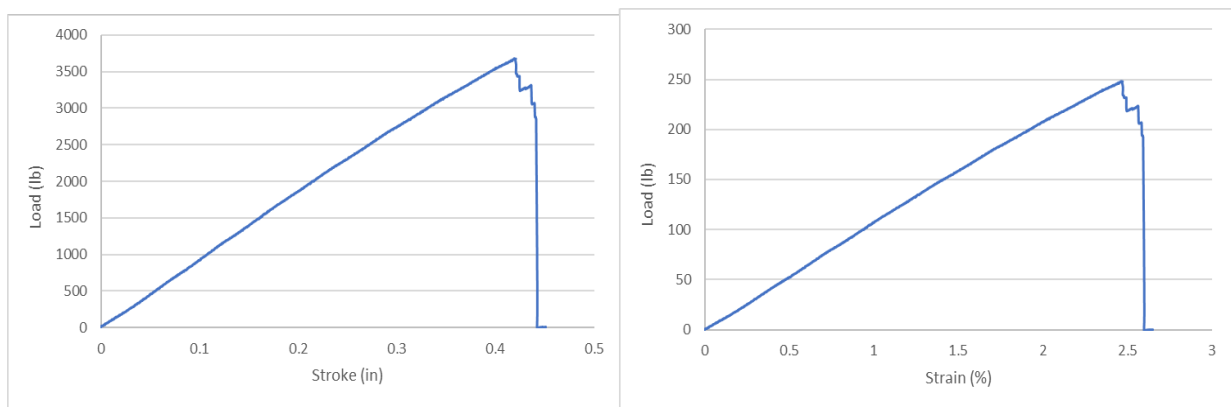

Figure 78 (Left) High temperature tensile testing set-up, (Right) environmental chamber.

#### 5.3.1 Tested sample grips located outside the environmental chamber

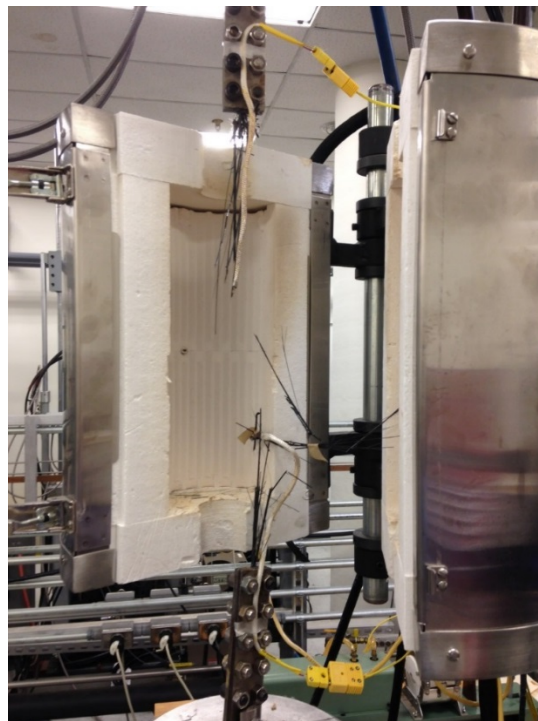

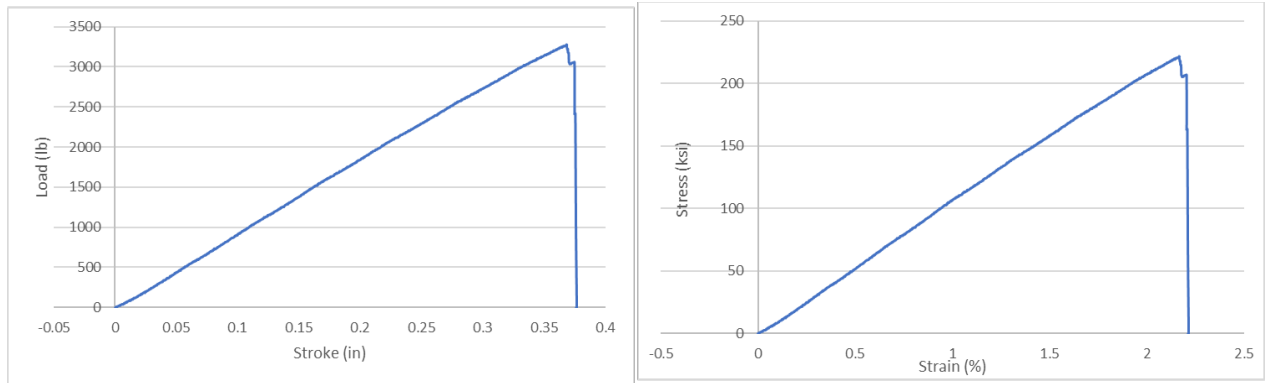

The first set of tensile testing on C7 core samples were performed with grip located outside the furnace and with gage section of 17-inch. The test results carried out at 100°C, 180°C, and 225°C are shown in Figure 79 and Figure 81, respectively.

**Figure 79 C7 core sample tensile test #3 at 100°C**

**Figure 80 C7 core sample tensile fractured at 180°C.**

**Figure 81 C7 core sample tensile fractured at 225°C.**

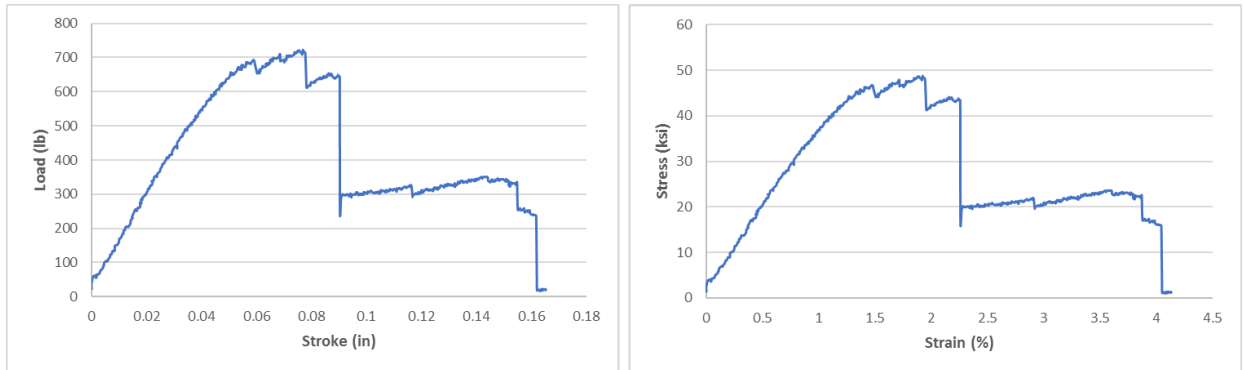

### 5.3.2 Sample grips located inside the environmental chamber

The second group of the C7 core sample tensile test were performed with the grip located inside the furnace. This scenario is more closed to that of C7 overhead conductor service environment, which was learned from EPRI HTLS thermal cycling experiment that showed higher temperature at conductor and grip interface within the splice connector at higher operating temperature. The temperature profiles obtained from thermal couples located at C7 core sample and grip are provided in Table 6, where the grip temperature is about 20°C lower than the C7 core sample temperature. The tensile test results are provided in Figures 82-89, which showed a significant drop in tensile strength at a temperature at or above 180°C compared to that of sample grips located outside the furnace. This phenomenon is primary due to C7 core sample softening above

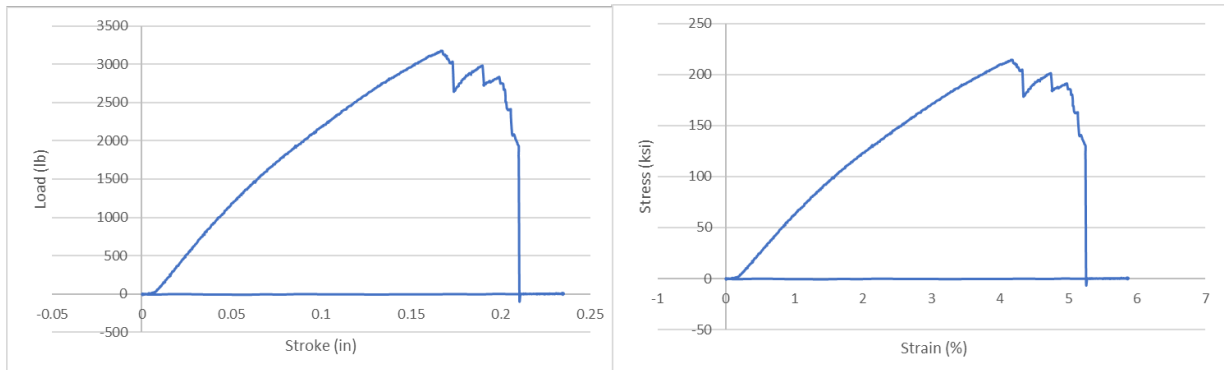

Tg induced grip slip during tensile testing. This lack of sufficient grip strength for C7 core samples may also indicate the potential weakness of applying the conventional crimping type core grip connector to the C7 carbon composite core wires designed for the high operating temperature. The Tg of PPS matrix is about 90°C for a C7 core sample, thus at 180°C operation temperature induced PPS matrix softening can cause PPS matrix flow out of high pressure crimping grip region. The consequence is the significant reduction in the grip or connector crimping strength.

**Table 6 Temperature profile of C7 core sample tensile testing**

Temperature, °C	
C7 core sample	Grip
99	86
125	104
180	161
225	202

## 6 OTHER APPROACHES USED FOR C7 COMPOSITE CORE THERMAL AGING CHARACTERIZATIONS

---

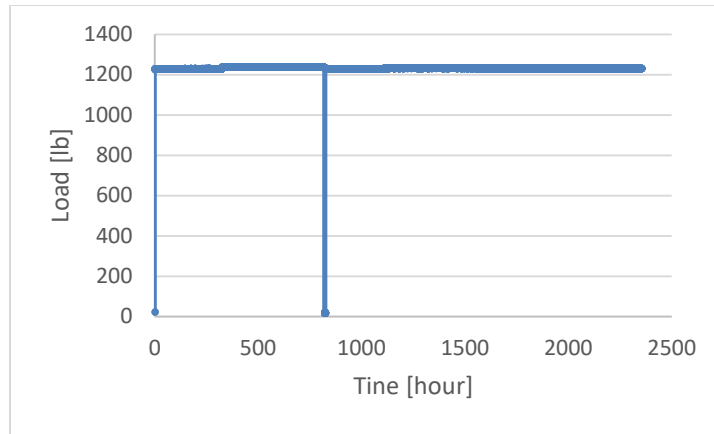

### 6.1 C7 carbon composite core sample creep testing

C7 composite core wire long-term creep response is another important high temperature material behavior that needs to be understood. The C7 core sample creep test setup is shown in Figure 90.

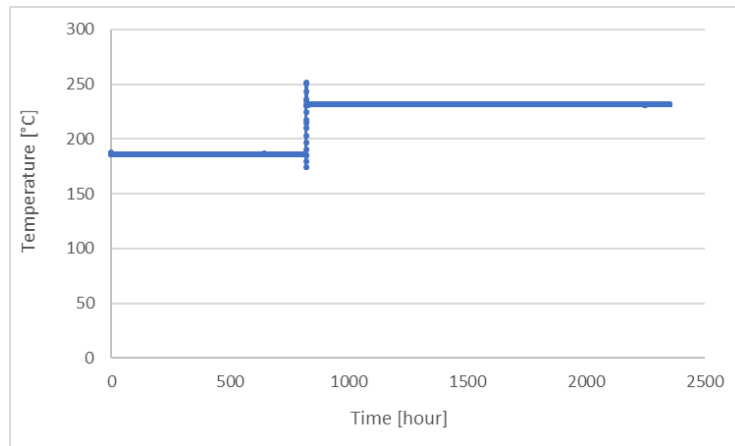

**Figure 90 (a) Creep test frame including environmental chamber, (b) C7 core creep test sample in the loading train with grip, thermal couples, and LVDTs, (c) Close look of the environmental chamber, where grip is located outside the chamber.**

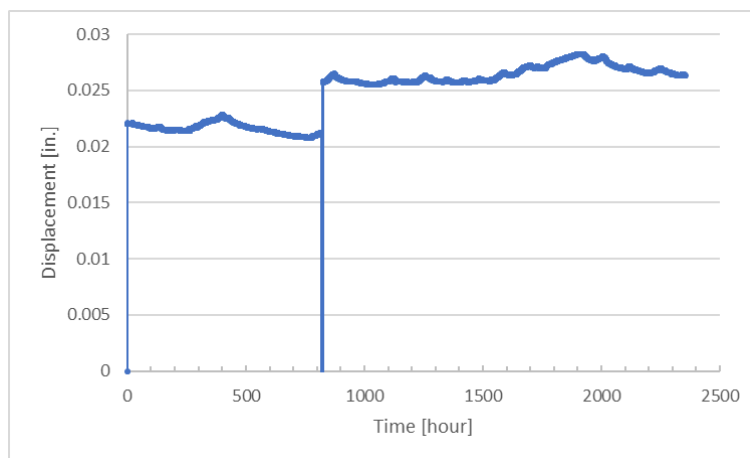

The creep test was performed with a load of 1200 lb. at 180°C for 819 hours and then started with the second creep test with a load of 1200 lb. at 225°C for another 1534 hours. The details of creep test time histories are provided in Figures 91-93. The associated creep strains at 180°C and 225°C are provided in Figure 94 and Figure 95, respectively. The estimate creep strain at the performed period is quite small, and the creep variation is mostly due to testing laboratory ambient temperature variability during the winter period.

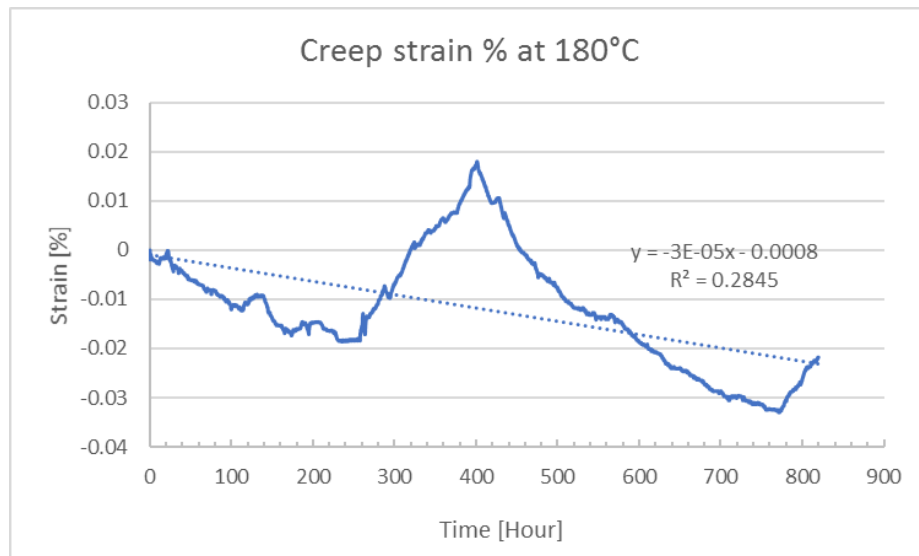

**Figure 91 Creep test load-time history.**

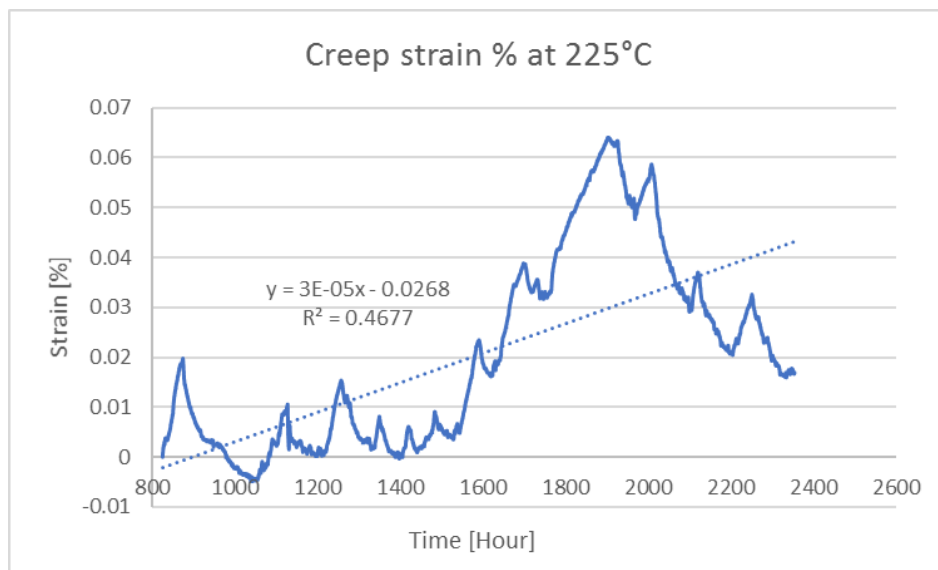

**Figure 92 Creep test temperature-time history.**

**Figure 93 Creep test displacement-time history.**

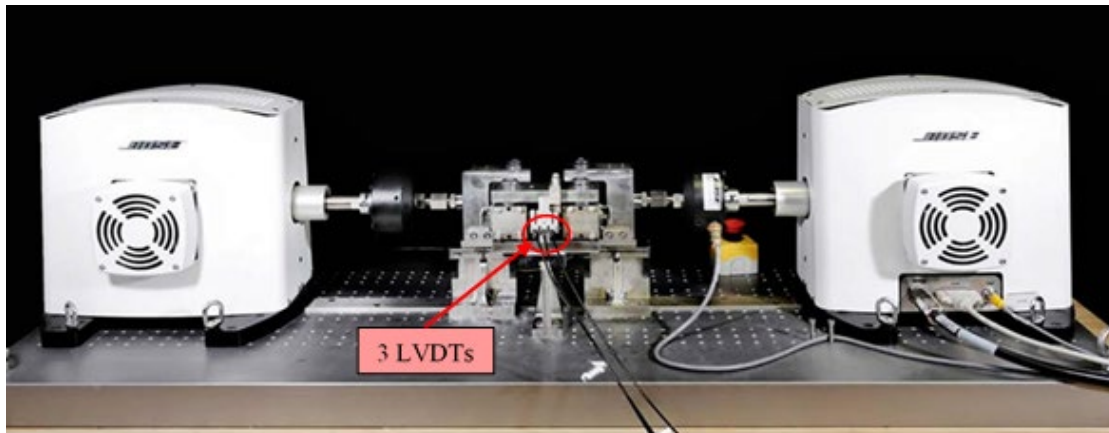

**Figure 94** Creep test strain-time history at 180°C, 26-inch long C7 core sample with 4-inch gage length. The estimated creep strain rate is -3E-05 %/hour.

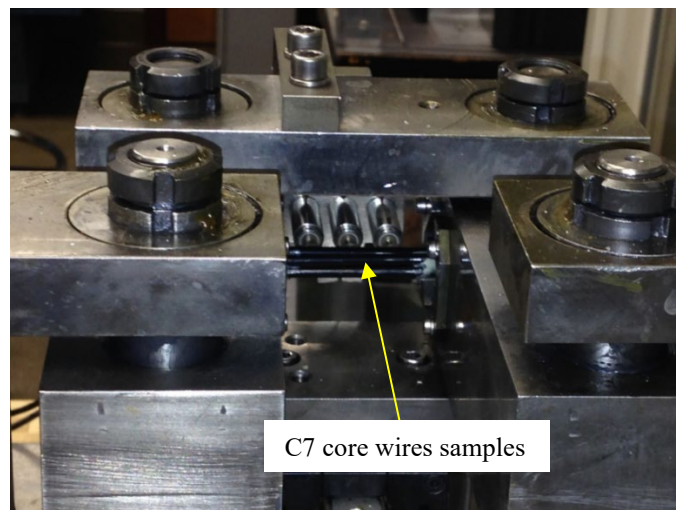

**Figure 95** Creep test strain-time history at 225°C, 26-inch long C7 core sample with 4-inch gage length. The estimated creep strain rate is 3E-05 %/hour.

## 6.2 C7 carbon composite core dynamic stability evaluation

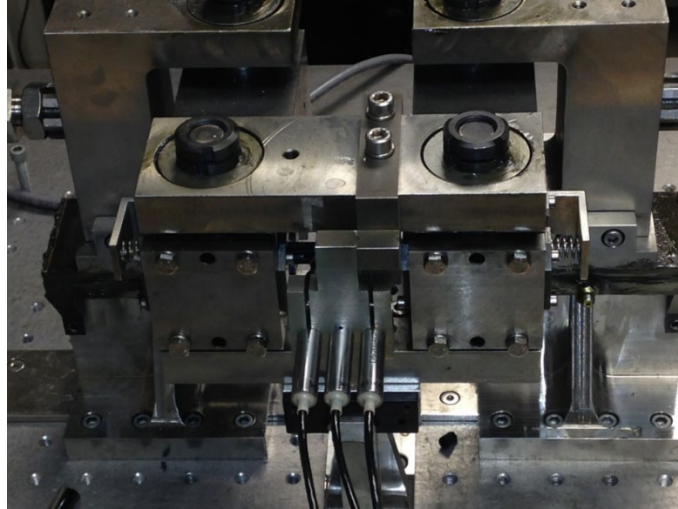

C7 composite core wire long-term vibration fatigue response is another important thermal-plastic composite material behavior that needs to be understood. C7 carbon composite core dynamic behaviors will be evaluated for both Aeolian and Galloping related vibrations simulation to estimate C7 composite core effective lifetime under vibration fatigue loading. The ORNL patented cyclic integrated reversible-bending fatigue tester (CIRFT) testing method will be used for C7 composite core dynamic reliability and stability study [9,10]. The C7 core sample creep test setup is shown in Figure 96. The real-time CIRFT fatigue test results of 12% RB bending moment loading under 1.6 million cycles are shown in Figures 97. Large noise observed from the test data is primary due to severe contact interaction among the 7 C7 core wires during reversible dynamic bending loading of  $\pm 5$  N-m range. From figure 97, no significant increase in mean curvature increases or reduction in the mean flexural rigidity under bending fatigue testing were observed after 1.6 M cycles. There, C7 core wires dynamic fatigue response was considered intact after 1.6 M cycles bending fatigue test.

## 7 DEVELOPING QUALIFICATION CRITERIA FOR C7 COMPOSITE CORE THERMAL PERFORMANCE

---

### 7.1 General considerations

The proposed qualification criteria development for the C7 composite core thermal stability at the target C7 overhead conductor operating temperature are covered by the followings two major efforts, namely, (1) C7 composite core glass transition temperature ( $T_g$ ) quantification, covered by TGA, DMA and TMA tests, and (2) C7 composite core material mechanical strength verification, covered by 3-point bending test, tensile test, creep test, and dynamic vibration test. The summary of the developed qualification test results, including DMA, TMA, 3-point bending and tensile tests, are provided in Tables 7-10.

Analysis of these qualification test results shows large data scatter due to inherited inhomogeneous and composite material characteristic. The general trend of the C7 composite core material testing response strongly depends on the followings:

- (1) The properties of the individual components; such as PPS, PEEK, and carbon fibers, where different  $T_g$  values were revealed from DMA test as shown in Table 7.
- (2) The relative quantities of different phases; such as the effect of carbon fiber volume ratio to the dynamic modulus evaluation in a DMA test.
- (3) The orientation of various components; such as carbon fiber uniaxial orientation, embedded within PPS matrix, and the outer coating layer PEEK provided circumferential constraint, and their integrated response will affect the effective C7 core sample system thermal expansion evaluation in a TMA test.
- (4) The degree of interface bonding between the polymer matrix/surface coating and the carbon fiber reinforcements; they will affect both DMA and TMA test results and the C7 core sample mechanical strength evaluation.
- (5) The loading rate dependent material behavior was also revealed from tensile test; where at higher loading rate a significant C7 core tensile strength reduction was observed. This may imply C7 core material behavior at high rate loading, such as galloping condition, deserve our special attention.
- (6) C7 composite core grip system induced lateral/circumferential constraint compressive residual stress fields; the loss of compressive residual stress to C7 composite core sample at high temperature can significantly reduce the C7 composite core system mechanical strength and C7 overhead conductor integrated performance at target operating temperature.

Further considerations on C7 composite core long-term operation stability, is that thermal plastics matrix composites can be affected by the irreversible property changes, induced by the following degradation agents:

1. Thermal - static heat aging, sub-zero exposure or thermal cycling;
2. Humidity (including hot/wet) exposures;

3. Complete immersion in water at ambient and elevated temperatures;
4. Freeze/thaw and dry/wet cyclic conditions;
5. Continuous or intermittent saltwater immersion or spray;
6. Weathering (including rain and sand erosion);
7. Combined load (i.e. stress) and environmental exposures;
8. Chemical (including water, fuel, acids, alkalis, solvents and oxygen);
9. Ultraviolet and high-energy radiation;
10. Electrical stress (e.g. lightning stress and galvanic reactions) and Micro-organisms.

## 7.2 Discussion

### 7.2.1 Transition Temperature Estimate for C7 Composite Core Material

Tg results from DMA & TMA Testing and lesson learned are stated below:

- From DMA Data
  - Tg range is from 85°C to 172.9°C w. r. t. flexural bending strength measurement.
- From TMA Data
  - Tg is around 160°C w. r. t. thermal expansion measurements.
- Tg serves as a temperature limit for C7 composite core high-temperature operation:
  - The Tg either from both DMA or TMA is lower than the C7 overhead conductor operation temperatures, specified by the vendor as stated below:
    - 180°C continuing operation, and
    - 225°C contingency operation.
- The glass transition temperature does not occur at a single temperature; and depends on the definition in use and method to measure, it can be defined as the temperature at which the material
  - (a) suddenly loses mechanical strength,
  - (b) exhibits a step-change in specific heat capacity, or
  - (c) exhibits increased thermal expansion.Thus, more definitions need to be considered depending on which properties are important for the end user.
- 85°C of C7 composite core is the limiting Tg set by PPS using DMA test methodology; this result is consistent with the lower end Tg value obtained from ORNL DMA tests.
- The lesson learned is that the contribution of PPS and PEEK to establish Tg criteria can be properly attributed under DMA testing with different loadings used in DMA tests.
- For the composite structure of C7 carbon composite core, the PEEK coating layer formed a protective layer around PPS composite matrix, which play a dominated effect w. r. t. C7 core sample thermal expansion displacement evaluation from a TMA test. This is the primary reason that C7 core Tg of 160°C estimated from TMA test is close to that of PEEK at 143°C.
- Therefore, Tg from TMA test was primary dictated by PEEK coating layer under low axial compression loading condition provided in TMA test; and the temperature increased beyond PPS Tg, the induced PPS matrix and carbon fiber composite structure changes won't be readily revealed due to exterior confinement provided by PEEK coating layer.
- The observed twin-peaks from Tan  $\delta$  of DMA method for Tg evaluations are consistent with that of the PPS and PEEK individual characteristic.

## 7.2.2 Mechanical strength verification at the target service temperature

The lesson learned from 3-point bending and tensile tests are stated below.

### **3-point bending test results**

- Baseline maximum flexural tensile stress is around 119 ksi to 139 ksi, the corresponding maximum strain range is around 0.83% to 1.31%.
- Maximum tensile stress range of the thermal aging samples is around 133 ksi to 184 ksi, and the corresponding maximum strain at failure is around 1.01% to 1.52% strain ranges.
- Thermal aging data shows the most material softening occurred at 225°C/100h aging temperature, with Young's modulus of 7.71E+6 psi; next softening occurred at 180°C/1000h with Young's modulus of 7.72E+6 psi. Significant deflection and ductility were also observed from these two thermal aging data.
- For EPRI thermal cycling aged samples, the maximum stress range is around 131 ksi to 153 ksi, and the corresponding maximum strain at failure is around 1.062% to 1.256%.
- The Young's modulus of thermal aging C7 core samples appeared to be less than that of the baseline C7 core samples.
- The average Young's modulus of tested C7 core samples is around 8.65 msi, which is about 30% to that of steel with 30 msi.
- EPRI thermal cycle aged C7 core tested data with O-temp conductor has higher deflection/ductility than that of Zr-Al conductor.

### **Tensile test results**

- The estimate average C7 core tensile strength is 206 ksi and the associated maximum strain is about 3.32% (with relatively large uncertainty), which is similar to that from Southwire data. And is compatible with that of ASTM B498/B802 high strength steel.
- C7 core sample tensile failure appears to be catastrophic brittle fracture, where C7 core sample upon failure was completely disintegrated into fibrous form under medium or low loading rate; while at very high loading rate C7 fail at much lower load compared to that of low or medium loading rate and C7 core sample failed in a brittle failure mode with the C7 core sample cross-section nearly intact.
- The estimate Young's modulus of baseline C7 core samples is around 7.22 msi and is about 24% to that of steel. Thus, a large deformation/displacement under load would be experienced by C7 core wire compared to that of conventional ACSS or ACSR steel core wire deformation.
- Tensile test results with 17-inch gage section sample show similar tensile strength with the baseline C7 core sample of 4-inch gage section, but, with much less ductility.
- The EPRI thermal cycle aged data with O-temp aluminum conductor appeared to have more ductility and softening w. r. t. Young's modulus reduction compared to that of Zr-Al conductor.

- The tensile strength of the C7 overhead conductor with O-temp aluminum conductor and with a dead-end connector shows about 8,000 lb. tensile load reduction compared to that of C7 overhead conductor w/o dead-end connector. About 5,000 lb. tensile load capacity reduction was also observed for C7 overhead conductor with Zr-Al conductor with dead-end connector. This could be interrelated as that potential C7 core wire damage through dead-end connector crimp forming process. Furthermore, postmortem examination also confirmed that the C7 overhead conductor failure site was within the dead-end connector region.
- In order to understand C7 core wire and the associated grip connector system performance under high-temperature operation, the C7 core sample tensile tests were also performed with the C7 sample grips located inside the furnace; where the grip temperature is about 20°C lower than that of C7 core samples. This C7 core wire-connector grip system temperature profile seems to resemble that of C7 overhead conductor in a high-temperature service environment. Furthermore, from EPRI HTLS thermal cycling experiments, the thermal couple's data show higher conductor-connector interface temperature at the splice connector region.

The associated tensile test results showed a significant drop in tensile strength and stiffness compared to that of sample grips located outside the furnace. And all the C7 core sample and the associated grip system show significant slip phenomenon during the tensile tests. This phenomenon is primarily due to C7 core sample softening above T<sub>g</sub> induced grip slip during tensile testing. This lack of sufficient grip strength for C7 core samples may indicate the potential weakness of applying the conventional crimping type core-grip connector system to the C7 carbon composite core wires designed for high-temperature operation. The T<sub>g</sub> of PPS matrix is about 90°C for a C7 core sample, thus at 180°C operation temperature the induced PPS matrix softening can cause PPS matrix flow out of high pressure crimping grip region. The consequence is the significant reduction in the grip or connector crimping strength for secure C7 composite core wires system.

- It is also interesting to note that tensile test results from samples with 17-inch gage section appeared to have the highest Young's modulus and the lowest ductility upon failure compared to the rest of tensile test results; and its maximum strain upon failure is about half of that from typical baseline sample with 4-inch gage section, even 17-inch gage section samples are all used for high-temperature tensile testing. The rationale of this observed low ductility phenomenon is that for a long composite sample it is expected to have more flaws contained in the gage section than that of a relatively short sample. Thus, the probability of a more uniform elongation during the tensile testing will be much less for a long sample compared to that of a relatively short sample.
- The average Young's modulus of C7 tensile test results is at 7.19 msi, which is about 27% to that of steel of 29 msi. The average thermal expansion coefficient of C7 core samples from TMA test around 180°C is about 6.176E-06/°C.

For a Drake conductor with span of 1000 ft span, and each core wire experienced with an average of 1500 lb. tensile load, the estimate thermal expansions for the core wire made of C7 composite core wire and the steel core wire at a 180°C operating temperature are detailed below.

(1) For C7 composite core wire – assumed perfect bond and no slip at grip connector

$$\begin{aligned}\text{C7 core wire expansion under load} &= \text{Length} * \text{Strain} = \text{Length} * \text{Stress}/E \\ &= 1000\text{ft} * (1500 / (3.14 * (0.136/2)^2) / 7.19\text{E}6) = 14.37\text{ft}\end{aligned}$$

$$\begin{aligned}\text{C7 core wire thermal extension} &= \text{Length} * \alpha * \Delta T = 1000\text{ft} * 6.176\text{E-}6 * (180-20) \\ &= 0.99\text{ft}\end{aligned}$$

The estimated C7 core wire total elongation is at 15.35 ft

(2) For steel core wire – at 180°C, E = 28 msi,  $\alpha = 11.5\text{E-}6/^{\circ}\text{C}$

$$\begin{aligned}\text{C7 core wire expansion under load} &= \text{Length} * \text{strain} = \text{Length} * \text{Stress}/E \\ &= 1000\text{ft} * (1500 / (3.14 * (0.136/2)^2) / 28.0\text{E}+6) = 3.69\text{ft}\end{aligned}$$

$$\begin{aligned}\text{C7 core wire thermal extension} &= \text{Length} * \alpha * \Delta T = 1000\text{ft} * 11.5\text{E-}6 * (180-20) \\ &= 1.84\text{ft}\end{aligned}$$

The estimated steel core wire total elongation is at 5.53 ft

Thus, at 180°C and 1500 lb. core wire load, C7 core wire overall expansion in 1000 ft span is about 2.8 times that of steel core wire. Thus, the consequence of much sever C7 overhead conductor sag is expected compared to that of ACSS or ACSR conductor.

For a Drake conductor with span of 1000 ft span, and each core wire experienced with an average of 1000 lb. tensile load, the estimate thermal expansions for the core wire made of C7 composite core wire and the steel core wire at a 180°C operating temperature are stated below.

(1) For C7 composite core wire – assumed perfect bond and no slip at grip connector

The estimated C7 core wire total elongation is at 10.57 ft

(2) For steel core wire – at 180°C, E = 28 msi,  $\alpha = 11.5\text{E-}6/^{\circ}\text{C}$

The estimated steel core wire total elongation is at 4.3 ft

Thus, at 180°C and 1000 lb. core wire load, C7 core wire overall expansion in 1000 ft span is about 2.46 times that of steel core wire.

## 8 SUMMARY

---

The general observation from the C7 composite core qualification testing protocols are the followings:

- (1) The estimate Tg for C7 composite core material from DMA and TMA tests are lower than the vendor's recommended 180°C and 225°C operation temperatures.
- (2) Higher thermal expansion coefficient, was observed from TMA test at post-Tg temperature range, for instance at 180°C the thermal expansion coefficient is about 3.6 times that of at ambient temperature.
- (3) Relatively low Young's modulus with mean value of 7.18 msi was observed from C7 core sample tensile test results, compared to that of steel with 29.0 msi.
- (4) C7 core grip effect induced C7 core strength reduction
- (5) At 180°C and a 1000 lb. core wire load, the estimate C7 core wire total expansion in a 1000 ft span is about 2.46 times that of steel core wire.
- (6) Due to sever C7 core wire extension under loads, in addition to the consideration of C7 core wire-core grip system performance deficiency at high temperature, the conventional ACSS or ACSR conductor seems to outperform the advanced C7 Overhead Conductor.

Based on the above observations, C7 Overhead Conductor does not match its claimed superiority as a new generation high-temperature low sag conductor for high voltage power transmission.

## 9 ACKNOWLEDGMENTS

---

The author would like to thank John Chan and Gary Sibilant of the Electric Power Research Institute (Charlotte, NC) for guidance and financial support. This project was funded by the EPRI High-Temperature Low Sag Conductor Program.

The author would like to thank Andres E. Marquez Rossy and Dana McClurg for DMA and TMA testing, Michael Lance for TGA testing, Shane Hawkins and Hong Wang for tensile and creep testing, and Randy Parten for machining components and sample preparation.
