DOLIB: DISTRIBUTED OBJECT LIBRARY

E.F. D’Azevedo
C.H. Romine

Abstract

This report describes the use and implementation of DOLIB (Distributed Object Library), a library of routines that emulates global or virtual shared memory on Intel multiprocessor systems. Access to a distributed global array is through explicit calls to \texttt{gather} and \texttt{scatter}. Advantages of using DOLIB include: dynamic allocation and freeing of huge (gigabyte) distributed arrays, both \texttt{C} and \texttt{FORTRAN} callable interfaces, and the ability to mix shared-memory and message-passing programming models for ease of use and optimal performance. DOLIB is independent of language and compiler extensions and requires no special operating system support. DOLIB also supports automatic caching of read-only data for high performance. The virtual shared memory support provided in DOLIB is well suited for implementing Lagrangian particle tracking techniques. We have also used DOLIB to create DONIO (Distributed Object Network I/O Library), which obtains over a 10-fold improvement in disk I/O performance on the Intel Paragon.
1. Introduction

Distributed memory multiprocessors have proven to be scalable and offer high performance. However, the limited memory on each processor node generally requires programers to perform their own data decomposition, carefully moving needed data among nodes by explicit message passing. Writing parallel application code using message passing is both intricate and error prone. Virtual shared memory enables a programmer to make full use of the total aggregate (gigabyte) memory resources while avoiding the difficulties of message passing.

DOLIB (Distributed Object Library) supports virtual shared memory on the Intel Paragon and iPSC/860 distributed memory supercomputers. DOLIB enables all processors to operate directly on any part of a distributed global array through explicit calls to \texttt{gather} and \texttt{scatter}. Advantages of using DOLIB include: dynamic allocation and deallocation of huge (gigabyte) distributed arrays, both C and FORTRAN callable interfaces, and the ability to mix shared-memory and message-passing programming models for ease of use and optimal performance. DOLIB is independent of any language or compiler extensions, and requires no special operating system support. DOLIB supports automatic caching of read-only data for high performance.

Section 2 discusses previous work related to DOLIB. In section 3, we describe the user interface in the form of manual pages for the DOLIB procedures. In section 4, we provide implementation details of DOLIB, to aid the programmer in optimizing the use of DOLIB’s global arrays. Section 5 illustrates the effectiveness and ease of use of DOLIB with a parallel matrix-matrix multiply. We have also used DOLIB to create DONIO, the Distributed Object Network I/O Library; details can be found in D’Azevedo and Romine [1]. DONIO obtains more than a 10-fold improvement in performance of concurrent disk I/O on the Intel Paragon. Finally, section 7 gives a short summary and a preview of upcoming developments in future versions of DOLIB.
2. Previous Work

The performance of virtual shared memory on a distributed memory system requires an effective caching strategy. Thus, much of the research into virtual shared memory, such as Li [2], Li and Hudak [3], and Stumm and Zhou [7], concerns intricate network protocols that maintain cache coherency in the presence of multiple concurrent updates.

Shiva [4] is a shared virtual memory system for the Intel iPSC/2 hypercube multiprocessor. Shiva uses the Memory Management Unit (MMU) page fault mechanism on each Intel i386 node to generate memory requests for remote pages. The implementation requires low level hardware and operating system support.

The CHAOS library [6] is an attempt to provide support for the parallel solution of irregular problems; that is, problems whose communication patterns are not easily predictable. CHAOS is a runtime library that can analyze the pattern of indirect addressing of arrays (such as \( x(ia(i)) = x(ia(i)) + y(ib(i)) \)), and automatically devise an optimized schedule of communication. CHAOS supports irregular assignment of data arrays to processors by using a globally accessible translation table to describe the location of elements of the array. The loop iterations are automatically partitioned (or repartitioned) and assigned to processors (based on trying to optimize the resulting load balance and communication volume). A preprocessing phase constructs the required communication schedules for the given distribution of workload and data.

DOLIB avoids the complexity of cache coherency by supporting a restricted virtual shared memory. Specifically, DOLIB assumes that any global array with caching enabled contains \textit{read-only} data. If the array is updated, it is the programmer’s responsibility to flush the cache to prevent erroneous results. In many important applications such as distributed finite element matrix assembly, parallel sparse matrix factorization and Lagrangian particle tracking, cache coherency is not an issue. For example, global data such as a flow field typically remains constant throughout a time-step for Lagrangian particle tracking. At the beginning of the next time step, the cache can be flushed to prepare for recomputing.
the flow field.

In section 4.1, we describe how caching is implemented in DOLIB, and discuss the DOLIB routines available to the user to control the cache.

3. User Interface

This section provides details on the syntax and behavior of each of the DOLIB primitives. They form the manual pages for DOLIB.
do_axpby

**do_axpby** performs a vector update \( y(list(i)) \leftarrow \alpha * x(i) + \beta * y(list(i)) \) operation into the global shared array \( y \).

**Synopsis**

```c
void do_iaxpby( int Iaf, int nsize, int *list,
    int *xarray, int ialpha, int ibeta )

void do_daxpby( int Iaf, int nsize, int *list,
    double *xarray, double dalpha, double dbeta )

void do_biaxpy( int Iaf, int nsize, int start,
    int *xarray, int ialpha, int ibeta )

void do_bdaxpy( int Iaf, int nsize, int start,
    double *xarray, double dalpha, double dbeta )
```

```fortran
subroutine doiaxpy( Iaf, nsize, list, xarray,
    ialpha, ibeta )
integer Iaf, nsize, list(nsize), xarray(nsize)
integer ialpha, ibeta

subroutine dodaxpy( Iaf, nsize, list, xarray,
    dalpha, dbeta )
integer Iaf, nsize, list(nsize)
real*8 xarray(nsize), dalpha, dbeta

subroutine dobiaxpy( Iaf, nsize, start, xarray,
    ialpha, ibeta )
integer Iaf, nsize, start, xarray(nsize)
integer ialpha, ibeta
```
subroutine dobdaxpby( Iaf, nsize, start, xarray,
    dalpha, dbeta )

integer Iaf, nsize, start
real*8 xarray(nsize), dalpha, dbeta

Input parameters

Iaf  - Iaf is the array descriptor obtained from do_declare.
nsize  - nsize is number of items involved in the vector update operation.
list  - list holds the index list for the vector update operation, for those versions of axpby that use it.
start  - start is the starting index into the global array referenced by Iaf for the vector update operation, for those versions of axpby that use it.
xarray  - xarray is the (local) buffer area that holds the values for the vector update operation.
ialpha, dalpha  - ialpha, dalpha is the scaling in xarray.
ibeta, dbeta  - ibeta, dbeta is the scaling in the global array.

Description

do_axpby (and all of its variants) performs a distributed vector update operation into the global shared array out of the specified buffer. The index set is described in list (do_daxpby), or is derived as a contiguous block of nsize elements starting at index start (do_bdaxpby). It is an error to have nsize ≤ 0.

The axpby operation can be used in assembly of finite element matrices into a global stiffness matrix. The accumulation of individual entries is performed as a critical section by the owner of the data page and hence eliminates the need for exclusive access or locking of the global array.
Note that the scatter operation can be implemented as a special case of an \texttt{axpby} update with $\alpha = 1$, $\beta = 0$.

This is not a synchronous call. The calling process does not wait (block) until the \texttt{axpby} request is completed. Note that it is an error to access past the declared array size, \texttt{gsize}, set in \texttt{do DECLARE}. 

**do setName**

`do declare` allocates a distributed global shared array and returns a descriptor to the distributed object. An implicit global synchronization is performed.

**Synopsis**

```c
void dodeclare( int *Iaf, char *name, int gsize,
               char *ctype, int pagesize, int blocksize )

subroutine dodeclare( Iaf, name, gsize, ctype,
                      pagesize, blocksize )

integer Iaf, gsize, pagesize, blocksize
character(*) name, ctype
```

**Input parameters**

- **name** - `name` is a *null terminated* character string that distinguishes the global array declared. It is used for displaying informative error messages. A null terminated string can be generated as `name = "arrayname" // char(0)` in FORTRAN.

- **gsize** - `gsize` is the number of items (not bytes) in the global array.

- **ctype** - `ctype` is a *null terminated* character string that describes the type of the global array. Valid string values are “int” or “integer”, “double”, “real*8” or “double precision” and “char” or “character” (all either lower or upper case).

- **pagesize** - `pagesize` is the number of items in a page.

- **blocksize** - `blocksize` is the number of pages in a block. Note there are `blocksize*pagesize` entries in a block.
Output parameter

Iaf - Iaf is a descriptor to the global shared array.

dodeclare returns a positive value in Iaf on success.

Discussion

dodeclare allocates a distributed global shared array and returns a descriptor (positive integer) to the distributed object. The array is composed of fixed-size pages grouped as blocks. If enabled, caching is performed on a page as a unit. The blocks are distributed among all processors in wrap-mapped fashion. Actual storage is obtained by malloc() in the C language.

Important note: indexing conforms to the conventions of the language being used. That is, a global array is indexed with 1:gsize in FORTRAN, 0:(gsize-1) in C. The region of memory is not initialized in any way — assume it is garbage.

All processors must participate in dodeclare. An implicit global synchronization is performed.
do_destroy

do_destroy deallocates global shared resources associated with the array descriptor. An implicit global synchronization is performed.

Synopsis

void do_destroy( int Iaf )

subroutine dodeestroy( Iaf )
integer Iaf

Input parameters

Iaf  - Iaf is the array descriptor obtained from do_declar.

Description

do_destroy deallocates the global shared resources associated with the array descriptor Iaf. Memory is returned to the heap by free() in the C language.

All processors must participate in do_destroy. An implicit global synchronization is performed.
**do_disable**

*do_disable* disables caching of data pages associated with the global array.

**Synopsis**

```c
void do_disable( int Iaf )

subroutine dodisable( Iaf )
integer Iaf
```

**Input parameters**

- **Iaf** - Iaf is the array descriptor obtained from *do_declare*.

**Discussion**

*DOLIB* supports automatic caching of data pages to reduce communication and enhance performance. *do_disable* disables caching of data pages in the global array associated with descriptor **Iaf**. All data pages associated with global array descriptor **Iaf** in the cache are purged.

*Important note:* it is the programmer’s responsibility to disable caching while the global array can be asynchronously updated. There is no implicit enforcement of cache coherency since only unmodified read-only pages should be cached.

Purging of data pages in the cache can be done by calling *do_disable* or by setting the cache size to be zero with *do_setchsize*. Caching can be turned on by calling *do_enable*. 
do_wait

**do_wait** blocks and waits till the asynchronous gather request is satisfied.

**Synopsis**

```c
void do_wait( int reqid )

subroutine dowait( reqid )
integer reqid
```

**Input parameters**

reqid - request descriptor returned from an asynchronous gather operation such as do_bgather or do_agather.

**Description**

do_wait blocks and waits until the data requested by an asynchronous gather has been copied into the user buffer. The request id reqid is released and invalidated after return from do_wait. Calling do_wait with an invalidated request id is an error.
do_enable

**do** enable enables caching of data pages associated with the specified global array.

**Synopsis**

```c
void do_enable( int Iaf )

subroutine doenable( Iaf )
integer Iaf
```

**Input parameters**

- **Iaf** - Iaf is the array descriptor obtained from **do_declare**.

**Discussion**

DOLIB supports caching of commonly used data pages to reduce communication and enhance performance. **do_enable** enables caching of read-only data pages in the global array associated with descriptor **Iaf**. Caching is performed on a page (determined by **pagesize** in **do_declare**) as a unit.

*Important note:* It is the programmer’s responsibility to ensure only read-only unmodified data is cached. There is no implicit enforcement of cache coherency since only unmodified read-only pages should be cached. Although not required, a global synchronization (**do_gsync**) is strongly recommended before calling **do_enable** to ensure correctness.

Purging of data pages in the cache can be done by calling **do_disable** or by setting the cache size to be zero with **do_setchsize**.
do_gather

do_gather performs a gather operation out of the global shared array into the specified buffer.

Synopsis

void do_gather( int Iaf, int nsize, int *list, void *buf )

subroutine doigather( Iaf, nsize, list, buf )

integer Iaf, nsize, list(nsize)
integer buf(nsize)

subroutine dodgather( Iaf, nsize, list, buf )

integer Iaf, nsize, list(nsize)
real*8 buf(nsize)

Input parameters

Iaf – the array descriptor obtained from do_declare.

nsize – number of items to be collected in the gather operation.

list – the index list for the gather operation.

buf – the buffer area to hold the result of the gather operation.

Description

do_gather performs a collect operation out of the global shared array into the specified buffer. The index set is described in list.

This is a synchronous call. The calling process waits (blocks) until the gather request is completed. Note that it is an error to attempt access beyond the declared array size, gsize, set in do_declare.
**do_bgather**

*do_bgather* performs an asynchronous block gather operation out of the global shared array into the specified buffer.

**Synopsis**

```c
int do_bgather( int Iaf, int nsize, int istart, void *buf )
```

```c
integer function dobigather( Iaf, nsize, istart, buf )
```

```c
integer Iaf, nsize, istart
```

```c
integer buf(nsize)
```

```c
integer function dobdgather( Iaf, nsize, istart, buf )
```

```c
integer Iaf, nsize, istart
```

```c
real*8 buf(nsize)
```

**Input parameters**

- **Iaf** — the array descriptor obtained from *do_declare*.
- **nsize** — number of items to be collected in the gather operation.
- **istart** — the starting index for the gather operation. Indices range from **istart** to **istart + nsize - 1** are collected.
- **buf** — the buffer area to hold the result of the gather operation.

**Description**

*do_bgather* performs an asynchronous block gather operation out of the global shared array into the specified buffer. The index set ranges from **istart** to **istart + nsize - 1**. This is an asynchronous call with the function returning an integer request descriptor to be used with *do_isavail* and *do_wait*. The buffer **buf** should be treated as invalid until either
do_isavail returns .true. or 1, or until do_wait is called. The calling process returns immediately without blocking. It is an error to attempt access beyond the declared array size, gsize, set in doDeclare.
**do_init**

*do_init* enables emulation of global shared memory. An implicit global synchronization is performed.

**Synopsis**

```c
void do_init( int myid, int nproc )
```

```fortran
subroutine doinit( myid, nproc )
```

```c
integer myid, nproc
```

**Input parameters**

- **myid** — the unique identifier for each processor, $0 \leq myid \leq (numproc-1)$. On Intel systems, myid can be obtained from the NX routine `mynode()`.

- **nproc** — nproc is the total number of processors. On Intel systems, numproc can be obtained from the NX routine `numnodes()`.

**Discussion**

*do_init* initializes the DOLIB library and enables the emulation of global shared memory. *do_init* must be called before any use of DOLIB routines.

An implicit global synchronization is performed.
do_isavail

do_isavail checks whether the data requested by an asynchronous gather are available.

Synopsis

```
int do_isavail( int reqid )

logical function do_isavail( reqid )

integer reqid
```

Input parameters

reqid – request descriptor returned from an asynchronous gather operation such as do_bgather.

Description

do_isavail returns .true. or 1 if the data requested by an asynchronous gather are available. The request descriptor reqid is released and is invalid as soon as do_isavail returns .true. or 1. Calling do_isavail with an invalid request descriptor is an error.
do_scatter

do_scatter performs a scatter (distributed copy) operation into the global shared array out of the specified buffer.

Synopsis

void do_scatter( int Iaf, int nsize, int *list, void *buf )

subroutine doiscatter( Iaf, nsize, list, buf )
integer Iaf, nsize, list(nsize)
integer buf(nsize)

subroutine dodscatter( Iaf, nsize, list, buf )
integer Iaf, nsize, list(nsize)
real*8 buf(nsize)

Input parameters

Iaf – the array descriptor obtained from do_declare.
nsize – number of items involved in the scatter operation.
list – the index list for the scatter operation.
buf – the buffer area that holds the values to be scattered.

Description

do_scatter performs a distributed copy operation into the global shared array out of the specified buffer. The index set is described in list. It is an error to have nsize ≤ 0.

This is an asynchronous call. The calling process does not wait (block) until the scatter request is completed. Note that it is an error for do_scatter to attempt to access beyond the declared array size, gsize, set in do_declare.
do_gsync

*do_gsync* performs an explicit global synchronization of all the processors. *When the* *do_gsync* *operation is completed, all previously called DOLIB operations are guaranteed to have completed.*

**Synopsis**

```c
void do_gsync()
```

**subroutine** dogsync

**Discussion**

The *do_gsync* routine synchronizes the processors and ensures that all active or pending DOLIB routines (including all *do_gather*, *do_scatter*, and *do_axpby* operations) have completed. *do_gsync* is useful for avoiding potential race conditions (such as when a *do_scatter* is immediately followed by a *do_gather*).

Application codes can freely mix DOLIB with other parallel programming primitives (such as PICL and PVM calls) when desired; however, before making calls to routines in these libraries, *do_gsync* should be called to purge processor buffers of any messages relating to DOLIB.
**do_check**

do_check causes the calling processor to check its message queue for any pending DOLIB requests. If any are found, they are processed before do_check returns.

**Synopsis**

```c
void do_check()
```

**subroutine docheck**

**Discussion**

The do_check routine causes the calling processor to satisfy all pending DOLIB requests in its message queue. do_check is a no-op in the Intel multiprocessor version of DOLIB, since the interrupt handler causes all incoming requests to be processed. However, for the polling version of DOLIB (see section 6), do_check is provided so that the programmer can prevent a starvation condition or increase the frequency with which DOLIB requests are handled to enhance performance.
**do_setchsize**

*do_setchsize* sets the size of the cache in terms of number of pages to be cached. *do_setchsize* returns the previous cache size.

**Synopsis**

```c
int do_setchsize( int npages )
```

```c
integer function dosetchsize( npages )
```

`integer npages`

**Input parameters**

`npages` - `npages` is the size of cache in terms of number of pages to be cached.

**Discussion**

*DOLIB* supports automatic caching of commonly used data pages to reduce communication message traffic and enhance performance. A common shared cache pool is used even though page size for each global array may be different. A larger cache would yield a better “hit ratio” but require more memory and entail a higher overhead for associative searching. The programmer can set the cache size appropriate for a specific application for optimal performance.

Note setting the cache size to be zero is a fast way of purging the entire cache.
4. Implementation Details

DOLIB is designed to provide support for globally shared arrays in a distributed-memory environment. In this section, we describe some of the design decisions made that may affect the performance of application codes that use DOLIB.

DOLIB views a large global array as composed of fixed size pages stored in a block wrapped fashion across all processors. This page structure simplifies caching, which is vital for good performance. The restriction to a block wrapped mapping allows DOLIB to easily find the location (processor number and machine address) of any array element. Pages can be easily malloc'ed or free'ed.

DOLIB for the Intel iPSC/860 and Paragon machines is implemented using the IPX (Inter Process eXecution) [5] system developed at Brookhaven National Laboratory.\(^1\) This version of DOLIB (and IPX) relies heavily on a reliable interrupt mechanism provided by hrecv on Intel multiprocessors. If a processor makes a call to do_gather, DOLIB first determines where (on which other processors) the requested data reside. For example, suppose that processor A requires data residing on processors B and C. do_gather causes processor A to send message requests that interrupt processors B and C from regular computation. These processors package the requested data and send reply messages back to Processor A. They then exit this “interrupt” mode and resume regular computation. At no time is the thread of regular computation “aware” of the interruption. However, when the interrupt mode is entered and assumes control of the processor, there may be two detrimental effects on the regular computation. First, data that reside in the hardware cache may be discarded during interrupt processing, thus increasing memory access time when regular computation is resumed. Second, if the regular computation involves pipelined floating point operations, the pipeline will be interrupted, thus increasing the overhead in reloading the pipe when regular computation is resumed.

The do_scatter operation involves a similar sequence of messages as the

---

\(^1\)IPX is available by anonymous FTP from the site msg.das.bnl.gov under the directory /pub/ipx.
do_gather.

The important facility provided by Intel’s hrecv primitive is that all such signals are caught. For example, if processor B in the example above receives another interrupt while processing the one from processor A, the new interrupt is queued and then processed before processor B returns to normal execution mode. We will discuss these operations in more detail later in this section.

We have also developed a version of DOLIB (based on a polling version of IPX) that does not require a preemptive interrupt mechanism. In section 6, we discuss the implementation of DOLIB in the absence of such reliable signal handling.

DOLIB must be initialized with a call to do_init before any other DOLIB calls can be made. The DOLIB routine doDeclare defines a new global shared array. The user provides: the global array size (total number of elements); the data type (double or real*8, int or integer, char or character); the number of data items per page (page size) and the number of pages per block (block size); and a name for the array (to allow for useful error messages), though accessing the array is always done through the array descriptor that is returned from doDeclare.

Since memory for the new global array is immediately allocated and the values of the resulting local data addresses are shared among the processors, doDeclare implicitly synchronizes the processors. Thus, all processors must participate in the doDeclare operation.

4.1. Caching

Caching is disabled by default when an array is declared. The DOLIB routine do_enable enables caching of the indicated array. There is a single cache for all the global arrays that have had caching enabled. The DOLIB routine do_setchsize can be used to specify the maximum size (number of cache pages) in the cache, which currently defaults to 128. The do_setchsize function returns the previous cache size. Note that for a given amount of memory there is a tradeoff between the number of cache pages allowed and the size of each page in the array. Both are chosen at run time, allowing the user to optimize the use of the cache for the
given application. Moreover, since the `pagesize` of a global array is set when it is declared, the pages in the cache may be of different sizes. For the Intel iPSC/860 and Paragon machines, a page size of 8Kbytes is reasonable.

Important note: Some patterns of accessing a global shared array may be unexpectedly memory-intensive. For example, consider a `do.gather` operation in which a single element of every page in the array is requested. The page containing each element is returned to the requesting processor, causing a copy of the entire global array to be temporarily created. For large arrays, such an operation may overflow the available memory, causing an error.

DOLIB makes no attempt to maintain cache coherency across processors. It is the user’s responsibility to ensure that any information that is cached is read-only. The user may flush the cache pages associated with any given array by calling `do.disable`. No implicit synchronization is done in `do.disable`, though the utility of selectively disabling caching of an array on some processors is unclear.

To illustrate the utility of `do.enable` / `do.disable`, consider the problem of tracking particles along characteristics of a changing flow field, where the flow field is stored in a global shared array. Throughout a given time step, the flow field is assumed constant (and hence, read-only data). After all particles have been tracked in the given time step, the flow field must be updated for the next time step. Since the flow field is no longer read-only data, the cache should be purged of the flow field by calling `do.disable`. After the new flow field has been computed and stored in the global array, caching can be re-enabled for the flow field with `do.enable`.

To purge the entire cache without the necessity of disabling caching on each global array individually, the user can simply set the cache size to 0 using `do.setchsize` (the previous value is returned by the function), and then reset it to its previous value.
4.2. Accessing a Global Shared Array

The main DOLIB routines that access the globally shared arrays are do_gather, do_scatter and do_axpby. The do_axpby routine implements the operation \( y \leftarrow \alpha x + \beta y \), where \( \alpha \) and \( \beta \) are constants, \( y \) is a globally shared array in DOLIB, and \( x \) is a local vector. do_axpby is a powerful and flexible primitive, and is commonly used in such contexts as finite element matrix assembly.

When a processor (say, processor A) calls the do_gather routine requesting a list of elements from a global shared array, the index list is processed to determine where the requested data reside. (If one of the contiguous block versions is called, the starting index and number of items is treated similarly). Items that are not local to processor A are obtained from other processors using the IPX get_array call. The information exchanged among the processors during the do_declare allows processor A to compute the machine address on the remote processors where the data reside. Using this address, the get_array call interrupts the remote processor, forcing it to return a message containing a copy of that data.

DOLIB provides both synchronous and asynchronous versions of the gather operation. The synchronous version causes the calling processor to block until the gather has been completed. The asynchronous version returns control immediately to the calling processor, providing a request descriptor as return value. The calling processor can then query the status of the asynchronous gather using do_isavail (with the request descriptor) to determine whether the gather has been completed. Calling do_wait will force the processor to block until the specified gather has been completed. The asynchronous call is provided to allow for overlapping of communication with computation; however, the user should be aware that there is some overhead associated with creating a request descriptor and allocating memory to contain the returned pages. The asynchronous version may be more expensive overall in cases where there is little chance of overlapping communication with computation.

Given a list of values for the local array \( x \) and a corresponding list of array indices for the global array \( y \), do_axpby accumulates the updated values to the
appropriate location in the global array. Global array references that reside on
the calling processor (say, processor A) are done directly by assignment to mem-
ory; the others require message passing, as follows: Processor A determines the
owner processor id, block number, page number and page offset for each array
reference, grouping those belonging to the same processor for efficiency. Then A
sends an interrupt message to each such processor (say, B and C), followed by
a message containing the necessary values and indices. The interrupt message
induces processors B and C to complete the do_axpby operation with the values
contained in the second message.

The procedure for implementing do_scatter is identical to that of the do_axpby
routine. Indeed, the DOLIB do_scatter routine is simply a do_axpby call with
$\alpha = 1$ and $\beta = 0$.

Warning: If a do_scatter operation is immediately followed by a do_gather
operation, a race condition may ensue, and old values (before the do_scatter
has completed) may be returned to the do_gather call. A do_gsync should be
called in between the do_scatter and do_gather to prevent this type of error.

4.3. Reclaiming Memory

One major advantage of DOLIB is the ability to dynamically create and destroy
global shared arrays. When an array is no longer needed, do_destroy will free all
memory allocated to the array, including cache pages associated with the given
array. To avoid inconsistent views of the array, the processors are first synchro-
nized (to ensure that any outstanding gather requests are satisfied), and then
the data structures for the array are destroyed. This implies that all processors
must participate in the do_destroy operation.

5. Performance of DOLIB on Intel iPSC/860

DOLIB is currently implemented using the IPX message system developed at
Brookhaven National Laboratory. IPX relies heavily on the hrecv() preemptive
interrupt capability on Intel multiprocessors. Access cost to emulated shared memory is due in part to the overhead in DOLIB, IPX and the underlying NX message delay. In this section, we illustrate the performance and use of DOLIB in the context of a parallel matrix-matrix multiply algorithm. The RATFOR source is included in the Appendix.

The algorithm computes the matrix product $C = A \times B$ where matrix $A$ is $N \times M$ and $B$ is $M \times M$ on $P$ processors. The computation proceeds by block row partition of $A$ among processors. Block columns in matrix $B$ are gathered to generate parts of matrix $C$ by calling the BLAS routine $\text{dgemm}$. The volume of communication for each processor is $O(NM/P)$ for gathering matrix $A$, $O(M^2)$ for gathering $B$ and $O(NM/P)$ for scattering results back to matrix $C$.

Tables 5.1 and 5.2 display the run time (in seconds) on an Intel iPSC/860 with 8Mbytes of memory on each node. The run times are measured by calling the NX $\text{dclock}()$ routine. The items $\text{gathA}$, $\text{gathB}$, $\text{scattC}$, $\text{dgemm}$ denote the maximum communication time among all processor to gather $A$, to gather $B$ to scatter $C$ and the computation time in the level 3 BLAS $\text{dgemm}$. The total time is the elapsed time from a $\text{gsync}()$ at the start of the algorithm to another $\text{gsync}()$ at the end.

The matrix dimension $N$ affects the data distribution of the global matrices $A$ and $C$ since data pages are assigned to processors in a wrapped fashion. If $N$ is exactly divisible by $P$ ($\text{mod}(N, P) = 0$), then all references to matrices $A$ and $C$ are satisfied locally on each processor without external communication. This is reflected in the faster times for the gather of $A$ and scatter of $C$ for $N = 1440, 19200$ in Table 5.1 and $N = 1920, 37440$ in Table 5.2.

6. Implementation of DOLIB using Polling

The version of DOLIB for the Intel iPSC/860 and Paragon machines relies heavily on the reliable interrupt handling capabilities of Intel’s multiprocessors. We have implemented a version of DOLIB that relies on explicit polling of the message queue to service DOLIB requests. However, there are several requirements imposed on

the user of this version of DOLIB.

First, every DOLIB routine starts by checking its receive queue for DOLIB requests that must be satisfied. Hence, as long as all processors are executing DOLIB routines on a regular basis, performance should be largely unaffected. However, if any of the processors fails to call DOLIB routines, it will not check its receive queue for DOLIB requests, thus starving any processors attempting to access its array elements. Note that this is not a problem under the Intel version of DOLIB, since the interrupt handler forces the processor to handle incoming requests. The do_check routine is provided to allow the programmer to force a processor to check its input queue for DOLIB requests. The do_check routine is a no-op under the Intel version of DOLIB.

Our initial port of DOLIB to PVM (using a translation of IPX) is complete; however, because the IPX get_array routine is unaware of data types and treats all arrays as a sequence of bytes, DOLIB assumes a consistent integer and double precision format. Hence, currently only heterogeneous networks containing machines that agree on these formats (such as Sun Sparcstations and IBM RS/6000's) are
supported. We are currently rewriting DOLIB to use the PVM3.3 message passing library directly. When this is completed, DOLIB will provide a shared-memory programming paradigm for a wide variety of platforms, including fully heterogeneous clusters of workstations.

7. Summary

We have described the design and implementation of DOLIB, a library of routines that support virtual shared memory on the Intel family of distributed memory machines. DOLIB provides access to globally shared arrays through the explicit use of gather and scatter primitives. Globally shared arrays are dynamically created and destroyed by the user application, thus allowing efficient use of the available aggregate memory on the multiprocessor. DOLIB also supports automatic caching of read-only memory, to increase the efficiency of global shared memory by reducing the amount of message passing required.

We provided two illustrations of the use of global shared memory: a matrix-matrix multiplication routine, and faster concurrent I/O using a library called DONIO. These examples show that global shared memory can be an effective means of providing the shared-memory programming paradigm on distributed memory machines.

8. Obtaining the Software

To obtain the source code for DOLIB, the reader should send email to the authors: efdazedo@msr.epm.ornl.gov or rominech@ornl.gov.

Acknowledgements

The authors would like to express appreciation to Bob Marr, Ron Peierls and Joe Pasciak for the IPX package, which simplified the development of DOLIB.
9. Appendix

In this appendix, we list FORTRAN source code to illustrate the use of the DOLIB primitives. The source code given here is for the matrix-matrix multiplication example discussed in section 5.
