MECHANICAL RESPONSE OF STITCHED T300 MAT/URETHANE 420 IMR COMPOSITE LAMINATES: PROPERTY/ORIENTATION DEPENDENCE AND DAMAGE EVOLUTION

S. Deng* and Y. J. Weitsman*

ABSTRACT

This report presents experimental and analytical results of investigations on the mechanical response of stitched T300 mat/urethane 420 IMR composite laminates with three different lay-up configurations. Tensile tests and short-term creep and recovery tests were conducted on the laminate coupons at various orientations. The X-ray photographic technique was adopted to detect the internal damage due to external loading history. The tensile data of laminates with antisymmetric and symmetric lay-ups indicated that lay-up sequences of cross-ply laminates do not have much influence on their tensile properties. However, misalignments within the stitch-bonded plies disturb the symmetry of intended quasi-isotropic laminates and thereby cause the mechanical properties to exhibit a certain amount of angular dependence. Classic lamination theory was found to be able to provide a very good prediction of tensile properties for the stitched laminates within linear range. Creep and recovery response of laminate coupons is greatly dependent on loading angles and load levels. The internal damage of laminate coupons is also directly related to loading angles and load levels as well as loading history.

1. INTRODUCTION

In the ongoing Automotive Composite Consortium (ACC)/Oak Ridge National Laboratory (ORNL) project "Durability of Carbon-Fiber Composites," stitched T300 mat/urethane 420 IMR composites are being explored as a potential class of materials for application in the automotive industry. The stitched T300 mat was made by stitching cross-ply dry preforms, consisting of layers reinforced by T300 graphite fibers, at a stitch angle of 45° about the longitudinal fiber direction and with spacings of 5 mm, as well as 3 mm. By assembling the above pairs of stitched plies and injecting them with urethane 420 IMR, the composite laminates were thus fabricated with several lay-up sequences.[†] As a result of anisotropy (orthotropy), the mechanical responses of the finished laminates under various loading conditions may vary with load directions. Similarly, the internal damage induced by external loading is also likely dependent on loading directions and load levels.

This report presents the experimental data obtained from stitched T300 mat/urethane 420 IMR composite laminates with three different lay-ups. These experiments include tensile tests, short-term creep and recovery tests at various orientations, and damage detection within the test coupons by means of X-ray photography. An analytical approach based on classical laminate theory is employed to predict the stiffness of the three laminates with regard to various loading orientations.

[†] A detailed description of the materials and their processing procedures can be found in Ref. [1].

2. MATERIALS AND EXPERIMENTS

2.1 MATERIALS

Three types of T300 stitched mat/urethane 420 IMR laminate plaques with $[45/-45]_6$ (antisymmetric), $[45/-45]_{3S}$ (symmetric), and $[0/90/45/-45]_S$ (quasi-isotropic) lay-ups were provided by ACC. A single $[45/-45]_6$ plaque (C7, by ORNL designation, with stitch spacing of 3 mm), measuring ~3 mm in thickness, was used in this study. This plaque has 12 layers of T300 stitched mats with the lay-up sequence shown in Fig. 1(a), and its fiber volume fraction is 41.5% according to ACC. Four $[45/-45]_{3S}$ plaques [C49, C53, C54 and C55 (ORNL) all with stitch spacings of 5 mm] with an average thickness of ~3 mm were subsequently tested. Each of these plaques also has 12 layers of T300 stitched mats with symmetric lay-ups, shown in Fig. 1(b). The fiber volume fractions for these plaques were 45.7%, 38.9%, 38.9% and 37.6%, respectively. Data for a quasi-isotropic lay-up were collected for the $[0/90/45/-45]_S$ plaque (TJB59) with eight layers of T300 stitched mats, shown in Fig. 2. This plaque had an average thickness of 2.0~2.2 mm. All the plaques were square, measuring 24 in. by 24 in. (609.6 × 609.6 mm).

2.2 TENSILE TESTS

Test coupons measuring 203.2 mm long and 25.4 mm wide (8 × 1 in.) were cut from the above plaques with different angles, ϕ , relative to the fiber longitudinal direction in the top ply, as shown in Figs. 1 and 2. Cross-ply glass fiber laminates with a thickness of 1.6 mm were adopted as tabs, which were glued on the two ends of test coupons using high-strength epoxy to prevent the possible damage caused by the grips of the testing machine. A finished test coupon prior to testing is illustrated in Fig. 3.

Tensile tests were conducted using an 810 MTS Material Testing System with a loading rate of 1.016 mm/min (0.04 in./min) at room temperature (23°C). An extensometer and strain gages were used for recording the strain data in both the longitudinal and transverse directions of the test coupons.

To study the influence of specimen size on the off-axial tensile properties of cross-ply laminates, six 2-in.-wide test coupons ($\phi = 45^\circ$), cut from laminate panels with symmetric lay-ups, were tested at the same condition as their 1-in.-wide counterparts to compare their tensile properties.

2.3 CREEP AND RECOVERY TESTS

These same tensile coupons were adopted for creep and recovery tests. The short-term creep and recovery tests were performed on the 810 MTS Material Testing System with a load control mode at various levels of fixed stresses. An MTS extensometer and strain gages were utilized to record the deformation response during creep loading followed by recovery on unloading. The foregoing tests involved 5 h of creep followed by 15 h of strain recovery. All the tests were performed at room temperature (23°C). The average creep rate was defined as the total strain increment divided by the corresponding increment of time, and the residual strain values at the end of the recovery period were considered to be permanent strains.

2.4 INTERNAL DAMAGE DETECTION

An X-ray photography technique was used to detect internal damage induced by stepwise load increments. Liquid penetrant (zinc iodide solution) was applied at various stages of loading, as well as after

the test was completed. Coupons were immersed in the penetrant solution for several hours to enhance the resolution of the X-ray images. X-ray exposure was conducted in an HP 43804N X-ray machine at 30 kvp for 1.5 min using Polaroid films. Progressive increments in load levels, in percentage of ultimate tensile strength (%UTS), were applied to the test coupons to capture the sequence of damage development. X-ray photographs were taken at each intermittent stage of load removal.

3. ANALYTICAL PREDICTION OF LAMINATE MECHANICAL RESPONSE

3.1 PREDICTION OF TENSILE MODULUS OF CROSS-PLY LAMINATES

According to classical laminate theory², the laminate force per unit length (N_i) is expressed as:

$$\begin{cases} N_x = A_{11}\varepsilon_x + A_{12}\varepsilon_y + A_{16}\gamma_{xy} \\ N_y = A_{12}\varepsilon_x + A_{22}\varepsilon_y + A_{26}\gamma_{xy} \\ N_{xy} = A_{16}\varepsilon_x + A_{26}\varepsilon_y + A_{66}\gamma_{xy} \end{cases} \quad (1)$$

where A_{ij} are the laminate stiffnesses, and ε and γ denote normal and shear strains.

For a uniaxial loading in the X-direction (i.e., longitudinal direction of test coupons, as shown in Figs. 1 and 2), the above equations give

$$\begin{cases} A_{11}\varepsilon_x + A_{12}\varepsilon_y + A_{16}\gamma_{xy} = N_x \\ A_{12}\varepsilon_x + A_{22}\varepsilon_y + A_{26}\gamma_{xy} = 0 \\ A_{16}\varepsilon_x + A_{26}\varepsilon_y + A_{66}\gamma_{xy} = 0 \end{cases} \quad (2)$$

Therefore, the longitudinal modulus of a test coupon under uniaxial tension can be reduced to read:

$$E_x = \frac{1}{n_p h_o} \left(\frac{N_x}{\varepsilon_x} \right) = \frac{I}{n_p h_o} \left(A_{11} - \frac{A_{12}^2 A_{66} + A_{66} A_{16}^2 - 2A_{12} A_{16} A_{26}}{A_{22} A_{66} - A_{26}^2} \right), \quad (3)$$

where h_o is the thickness of a lamina and n_p is the total number of plies. The laminate stiffnesses A_{ij} are related to the ply stiffnesses Q_{11} , Q_{22} , Q_{12} and Q_{66} , which were determined previously³ and are listed in Table 1 below:

Table 1. Material parameters used for estimating basic properties of an individual lamina within stitched T300 mat/urethane 420 IMR cross ply coupons

h_o (mm)	Q_{11} (GPa)	Q_{22} (GPa)	Q_{12} (GPa)	Q_{66} (GPa)
0.25	88.97	0.72	3.10	3.30

For cross-ply laminates the relations between A_{ij} and Q_{ij} are as follows:²

$$\begin{aligned}
A_{11} &= A_{22} = 6h_o \left[(m^4 + n^4)(Q_{11} + Q_{22} + 4m^2n^2)(Q_{12} + 2Q_{66}) \right] \\
A_{12} &= 6h_o \left[2m^2n^2(Q_{11} + Q_{22}) + 2(m^4 + n^4)Q_{12} - 8m^2n^2Q_{66} \right] \\
A_{16} &= -A_{26} = 6h_o \left[(m^3n - mn^3)(Q_{11} + Q_{22}) + 2(mn^3 - m^3n)(Q_{12} + 2Q_{66}) \right] \\
A_{66} &= 6h_o \left[2m^2n^2(Q_{11} + Q_{22}) - 4m^2n^2Q_{12} + 2(m^2 - n^2)Q_{66} \right]
\end{aligned} \tag{4}$$

In this series of equations (4), $m = \cos(\phi)$ and $n = \sin(\phi)$, where ϕ denotes the angle between the directions X and X_1 , shown in Fig. 1. The value of the ply thickness h_o is also listed in Table 1.

3.2 ESTIMATION OF DISCREPANCY IN TENSILE PROPERTIES CAUSED BY LAY-UP MISORIENTATIONS FOR QUASI-ISOTROPIC LAMINATES

A major characteristic of quasi-isotropic lay-ups is that their in-plane stiffnesses do not depend on orientation. Nevertheless, such angular dependence was noted experimentally in the nominally quasi-isotropic plaques tested here. To trace the cause for the discrepancy, consider the circumstance where the inner $[\pm 45^\circ]$ ply groups were tilted by an angle α about their proper directions during the manufacturing process as shown in Fig. 4. Straightforward manipulations of laminate equations yield the following expressions (where $\alpha = 0$ stands for perfect quasi-isotropic lay-up):

$$\begin{aligned}
A_{11} &= A_{22} = \frac{1}{2h_o} (Q_{11} + Q_{22}) \left\{ \cos^4\phi + \sin^4\phi + \frac{1}{2} + \frac{1}{2} \sin^2[2(\alpha + \phi)] \right\} + \\
&+ \frac{1}{2h_o} (Q_{12} + 2Q_{66}) \left\{ \sin^2(2\phi) + \cos^2[2(\alpha + \phi)] \right\} \\
A_{12} &= \frac{1}{4h_o} (Q_{11} + Q_{22} - 4Q_{66}) \left\{ \sin^2(2\phi) + \cos^2[2(\alpha + \phi)] \right\} + \\
&+ \frac{1}{h_o} Q_{12} \left\{ \cos^4\phi + \sin^4\phi + \frac{1}{2} + \frac{1}{2} \sin^2[2(\alpha + \phi)] \right\} \\
A_{16} &= -A_{26} = \frac{1}{8h_o} (Q_{11} - Q_{22} - 2Q_{12} - 4Q_{66}) \left\{ \sin(4\phi) - \sin[4(\alpha + \phi)] \right\} \\
A_{66} &= \frac{1}{4h_o} (Q_{11} + Q_{22} - 4Q_{12}) \left\{ \sin^2(2\phi) + \cos^2[2(\alpha + \phi)] \right\} + \frac{1}{h_o} Q_{66} \left\{ \cos^2(2\phi) + \sin^2[2(\alpha + \phi)] \right\}
\end{aligned} \tag{5}$$

The longitudinal modulus E_x of coupons orientated at an angle ϕ about the direction X_1 can subsequently be calculated using Eq. (3).

4. RESULTS AND DISCUSSION

4.1 TENSILE PROPERTIES OF CROSS-PLY LAMINATES

Tensile data for $[45/-45]_6$ (antisymmetric) T300 stitched mat/urethane 420 IMR laminate coupons are summarized in Table 2, while tensile results for $[45/-45]_{3s}$ (symmetric) laminate coupons are presented in Table 3. The tensile strength is defined by the peak load divided by cross-section area, and the strain

corresponding to the tensile strength is taken as the failure strain. Typical stress-strain curves are shown in Fig. 5 for the $[45/-45]_6$ and in Fig. 6 for the $[45/-45]_{3S}$ coupons.

Table 2. Tensile data for $[45/-45]_6$ (antisymmetric) T300 stitched mat/urethane 420 IMR laminate coupons^a

Orientation angle (deg)	Stiffness (GPa)	Tensile strength (MPa)	Failure strain (%)	Poisson's ratio

75	24.8±4.5	229.5±4.3	1.31±0.32	0.229±0.058

Comparisons of tensile strength, stiffness, and failure strain for the foregoing two types of lay-ups are shown in Figs. 7, 8, and 9, respectively, with bars indicating data scatter.

The above results show that the stress-strain curves, stiffnesses, and strengths are essentially the same for both lay-ups, with tensile properties strongly dependent on loading angles. From Fig. 9, note that the $[45/-45]_{3S}$ laminate at loading angle $\phi = 45^\circ$ gives a higher value of failure strain, which may be attributed to its symmetric lay-up configuration.

A comparison of the laminate stiffness obtained from theoretical predictions and the experimental results is shown in Fig. 10. It can be seen that computational results of tensile modulus based on classic laminate theory are in good agreement with the experimental results for both of types of $[\pm 45^\circ]$ laminates.

4.2 EFFECT OF SPECIMEN SIZE ON OFF-AXIAL TENSILE PROPERTIES OF CROSS-PLY LAMINATES

An experimental investigation was conducted to assess the effect of specimen width on the tensile properties of $[\pm 45^\circ]$ lay-ups. For this purpose, coupons were cut from the same cross-ply laminate panel

with widths of 50.8 mm (2 in.) and 25.4 mm (1 in.), respectively. Results from tensile tests are listed in Table 4. The average tensile strength for the 2-in.-wide coupons was about 10% higher than that of their 1-in.-wide counterparts as shown in Fig. 11. The average failure strain for the 2-in.-wide specimens exceeded that of the 1-in.-wide coupons by about 13%. However, the values of tensile modulus and Poisson's ratio were nearly the same for both types of specimens. One plausible explanation for the disparity in the strength between the two sets of coupons can be made using the schematic drawings shown in Fig. 12, which shows that the 1-in.-wide coupon has twice as many unconstrained fibers as the 2-in.-wide coupon, when both specimens are of equal length.

Table 4. Comparison of tensile data for [45/-45]_{3S} (symmetric) T300 stitched mat/urethane 420 IMR laminate coupons with two specimen widths ($\phi = 45^\circ$)

Specimen Code	Stiffness (GPa)	Tensile strength (MPa)	Failure strain (%)	Poisson's ratio
2-in.-wide coupons				
C54-2in45-1	10.3	173.8	11.03	0.797
C54-2in45-2	10.4	168.2	9.73	0.763
C54-2in45-3	10.0	164.6	10.58	0.715
C54-2in45-4	11.0	160.7	10.17	0.769
C54-2in45-5	9.6	177.5	11.22	0.797
C54-2in45-6	9.2	175.7	16.30	0.882
Average	10.1±0.7	170.1±6.7	11.51±2.41	0.787±0.055
1-in.-wide coupons				
C54-1in45-1	11.3	169.5	11.08	0.799
C54-1in45-2	9.8	148.7	10.43	0.742
C54-1in45-3	9.4	149.6	10.65	0.761
C54-1in45-4	10.1	144.6	7.23	0.704
C54-1in45-5	10.8	160.5	10.00	0.692
C54-1in45-6	9.0	156.3	10.49	0.855
Average	10.1±0.9	154.9±9.2	9.98±1.39	0.759±0.061

It may be recalled that under monotonically increasing tensile loading of coupons oriented obliquely to the load direction, the stress-strain relationship changes gradually from linearity to nonlinearity, as shown in Figs. 5 and 6. Within the linear elastic range, which occurs at the early stage of loading, the deformation is not effected by constraint conditions. However, when the applied stress exceeds the elastic limit of the matrix and/or the shear strength of fiber-matrix interface, inelastic deformation occurs, and the unconstrained fibers within the specimen will either slip or rotate by means of a "scissoring action" until the attainment of shear failure. Weak locations are likely to develop within the unconstrained region, where tensile failure does occur. Consequently, the presence of a larger number of unconstrained fibers in the 1-in.-wide specimens would result in the lowering of both strength and failure strain, when compared to the instance of 2-in.-wide specimens. Conversely, note that the recorded increase in the strength of wider [$\pm 45^\circ$] graphite/epoxy coupons has been attributed by others to gripping effects.⁴ Because both tensile modulus and Poisson's ratio were determined within the linear range of stress-strain curves, little or no difference in these values is expected for both types of specimens.

4.3 TENSILE PROPERTIES OF [0/90/45/-45]_s (QUASI-ISOTROPIC) LAMINATES

Tensile data for the nominally [0/90/45/-45]_s (quasi-isotropic) laminate are shown in Table 5. Typical stress-strain curves for the test coupons at different loading angles are shown in Fig. 13. The tensile moduli that correspond to the experimental data are shown in Fig.14, together with data scatter bands, where they are compared against the value of the ideal quasi-isotropic laminate.

According to laminate theory, tensile properties of quasi-isotropic laminates should not depend on load direction. However, some differences in tensile properties and deviations from the predicted values have been found for various loading angles. The plausible explanation is that these differences were induced by small misalignment of plies in the laminates, due to misalignments in the original stitch-bonded mats. As shown in Fig. 4, assuming a misalignment angle α , the tensile moduli at different loading angles can be calculated by Eqs. (5) and (3). Figure 15 exhibits calculated values of laminate stiffnesses at different loading orientations, with α varying from 0° up to 20°. It is evident that, with increasing the lay-up misalignment angle α , the tensile moduli depart more significantly from the ideal value of $\alpha = 0^\circ$. Accordingly, lay-up misalignment has a significant effect on the mechanical response of laminates, and the accuracy in lamina alignment during the lay-up process is of key importance for attaining the desired properties of laminates.

Table 5. Tensile data for [0/90/45/-45]_s (quasi-isotropic) T300 stitched mat/urethane 420 IMR laminate coupons loaded at various orientations

Orientation angle (Degree)	Stiffness (GPa)	Tensile strength (MPa)	Failure strain (%)
0	34.4±1.6	335.7±5.2	0.96±0.05
15	30.4±0.9	252.0±32.0	0.86±0.11
30	26.9±0.8	277.7±5.0	1.09±0.03
45	33.7±0.9	308.6±15.8	0.92±0.04
90	31.5±1.0	307.0±7.8	0.96±0.03

Note, however, that the results shown in Fig. 15 correspond to the assumed misaligned configuration depicted in Fig. 4. This configuration may or may not correspond to the actual misalignments that occur during the lay-up process. Due to practical limitations, it is only possible to measure the angular misalignment between the exposed outer layers of the laminate. Nevertheless, an analysis of the "idealized" misaligned lay-up shown in Fig. 4 can provide a reasonable correlation with the magnitude of misalignment angles that occurred during actual lay-up processes*.

It can be seen that the ratio between the maximum and minimum stiffness values in Fig. 14 is about 0.78; according to Fig. 15, this ratio is 0.79 when the misalignment angle is $\alpha = 10^\circ$. This implies that there may have been a $\sim 10^\circ$ departure from ideal quasi-isotropic lay-up within the laminate panel that was tested in this study. Such angular deviations were indeed observed between the directions of fibers in the outer plies of the laminate.

* Although a wide scope of probabilities exists for the locations of the misaligned plies, the in-plane stiffnesses of the laminate are highly insensitive to any particular ordering of those locations within the laminate.

4.4 COMPARISON OF TENSILE PROPERTIES OF THREE LAMINATES WITH DIFFERENT LAY-UPS

Tensile strength, failure strain, and stiffness of the three laminates with different lay-ups were re-plotted together and are shown in Figs. 16, 17, and 18. As noted earlier, all the tensile properties for $[\pm 45^\circ]$ laminates vary greatly with respect to loading angles, but this angular dependence is less pronounced for the quasi-isotropic lay-ups. The angular dependence, which is nevertheless observed in the response of the latter circumstance, is attributed to misalignments in laminate lay-ups, as discussed above. Tensile coupons with a quasi-isotropic lay-up also show lower values of failure strain, when compared to the other two types of laminates. This disparity in failure strains is consistent with the failure behavior of the three laminates. From the tensile stress-strain curves shown in Figs. 5, 6, and 13, sudden failures occurred in tension of $[45/-45]_6$ and $[45/-45]_{3S}$ laminates at $\phi = 0^\circ$ and 90° , as was the case for the $[0/90/45/-45]_S$ laminate under all loading angles. Conversely, the delayed failures observed for $[45/-45]_6$ and $[45/-45]_{3S}$ laminates at loading angles ϕ , other than 0° and 90° , resulted in higher values of failure strains.

4.5 INTERNAL DAMAGE DEVELOPMENT UNDER EXTERNAL LOADING

To identify the influence of stress levels on internal damage of laminate coupons, test coupons were subjected to progressively stepped-up load levels [in percentage of ultimate tensile strength, (%UTS)]. Upon reaching the desired stress level, the load was maintained for 4 min, when penetrating liquid was applied on surfaces of the coupon, especially on edges. As noted earlier, the load was subsequently removed, and the coupon was immersed in the penetrant liquid for several hours. The x-ray photographs were then taken, and the specimen was reloaded to the next stress level.

For the tensile coupons with large loading angles such as $\phi = 45^\circ$ (-45°) or 30° (60°), extensive internal damage was accumulated prior to final failure. The stress-strain curves of two specimens with loading angle $\phi = 45^\circ$ are shown in Fig. 19, and their corresponding X-ray images are presented in Figs. 20(a) and (b). Stress-strain curves for both specimens show gradual flattening with increasing stress levels, indicating degradation of the materials due to prior loading history. The x-ray images also clearly show flaws developing in the two test coupons at stress levels above 40%UTS.

Loading-unloading cycling with successively increasing stress levels was also carried out on several specimens to investigate the process of internal damage growth. Typical loading-unloading stress-strain curves for a $[45/-45]_{3S}$ laminate coupon, with loading oriented at $\phi = 45^\circ$, are shown in Fig. 21. With increasing load levels, both the areas enclosed within the stress-strain curves ("hysteresis loops") and the residual strains increase as well, attesting to growth in irreversible internal damage mechanisms. Prior loading histories also reduce the stiffness of tensile coupons. This is shown in Fig. 22, where stiffness reduction of three test coupons is plotted vs the highest level of prior tensile stress applied to the specimen. These coupons are the same specimens shown in Figs. 19 and 21.

For tensile coupons tested at smaller loading angles, such as $\phi = 0^\circ$ (90°) or 15° (75°), the stress-strain relationship is nearly linear up to final failure, as exhibited by the corresponding curves in Figs. 5 and 6. In such cases, no extensive internal damages were recorded in X-ray photographs. Typical X-ray images are shown in Fig. 23 for a cross-ply specimen at a loading angle $\phi = 15^\circ$. No perceptible damage was detected even at a stress level as high as 60%UTS.

For the tensile coupons with quasi-isotropic lay-ups, the stress-strain curves at all loading angles are nearly linear until failure, as shown in Fig. 13. Loading-unloading curves of a typical quasi-isotropic coupon are shown in Fig. 24, and the corresponding X-ray photographs are illustrated in Fig. 25. The

coupon shows insignificant residual strains upon unloading and little or no hysteresis loops due to load cycling. These observations imply that the deformation of the specimen under tensile load is mainly elastic and that final failure is likely triggered by the sudden failure of the fibers. The above suppositions are supported by the X-ray photographs shown in Fig. 25, which exhibit no noticeable damage even when the loading stress is as high as 90%UTS.

The failure behavior of cross-ply tensile coupons with large loading angles, namely $|\phi| \geq 30^\circ$, where the fibers are oriented obliquely to the load directions, appears to be dominated by failure processes within the matrix resin, as well as by the bonding strength of fiber-matrix interface. Consequently, the mechanical response of the above specimens is time-dependent, as is commonly the case for polymer materials. However, for the tensile coupons with small loading angles, as well as for quasi-isotropic coupons at all angular orientations, failure is dominated by the fibers, which are linearly elastic in nature. Therefore, the stress-strain curves for these kinds of specimens are nearly linear up to failure.

4.6 CREEP AND RECOVERY BEHAVIOR OF CROSS-PLY LAMINATE COUPONS

4.6.1 Influence of Creep Stress Levels

The creep and recovery behavior of cross-ply laminate coupons was found to be highly influenced by the level of applied creep stress. Typical creep and recovery curves of $[45/-45]_{3S}$ laminate coupons under various creep stresses at a loading angle $\phi = 45^\circ$ are shown in Fig. 26. Generally, both creep rates and amplitudes of residual (permanent) strains increase with the magnitude of applied stress. High creep stresses also cause extensive internal damage within the coupons as shown by the X-ray images in Fig. 27. This figure exhibits the growing defects induced by increase in creep loads.

4.6.2 Influence of Loading Angles

Creep and recovery responses under increasing loading angles for the $[\pm 45^\circ]$ coupons resemble the behavior observed under increasing tensile stresses. Creep and recovery curves for four laminate coupons subjected to stresses of 60%UTS with different loading angles are presented in Fig. 28. Creep rates and residual permanent strains were found to increase with loading angles. Coupons with small loading angles, such as $|\phi| \geq 15^\circ$, give a more rapid recovery of creep strains.

5. CONCLUDING REMARKS

A systematic experimental and analytical investigation of the mechanical response of stitched T300 mat/urethane 420 IMR composite laminates revealed the following:

1. Tensile properties of $[45/-45]_6$ (antisymmetric) and $[45/-45]_{3S}$ (symmetric) laminates are strongly dependent on loading directions, but this dependence is much weaker for the nominally $[0/90/45/-45]_S$ (quasi-isotropic) laminates.
2. Lay-up sequences of cross-ply laminates do not seem to influence their tensile properties.
3. Misalignment of plies, occurring during the fabrication of quasi-isotropic laminates, reduces their tensile properties and induces angular dependence in stiffness values, which may deviate from intended properties of ideal quasi-isotropic laminates.
4. Classical laminate theory is capable of predicting the tensile properties of stitched laminates within linear range.

5. Internal damage of laminated coupons depends on loading history, applied stress, and loading angle.
6. The creep and recovery response of laminate coupons is dependent on both applied load level and loading angle.
